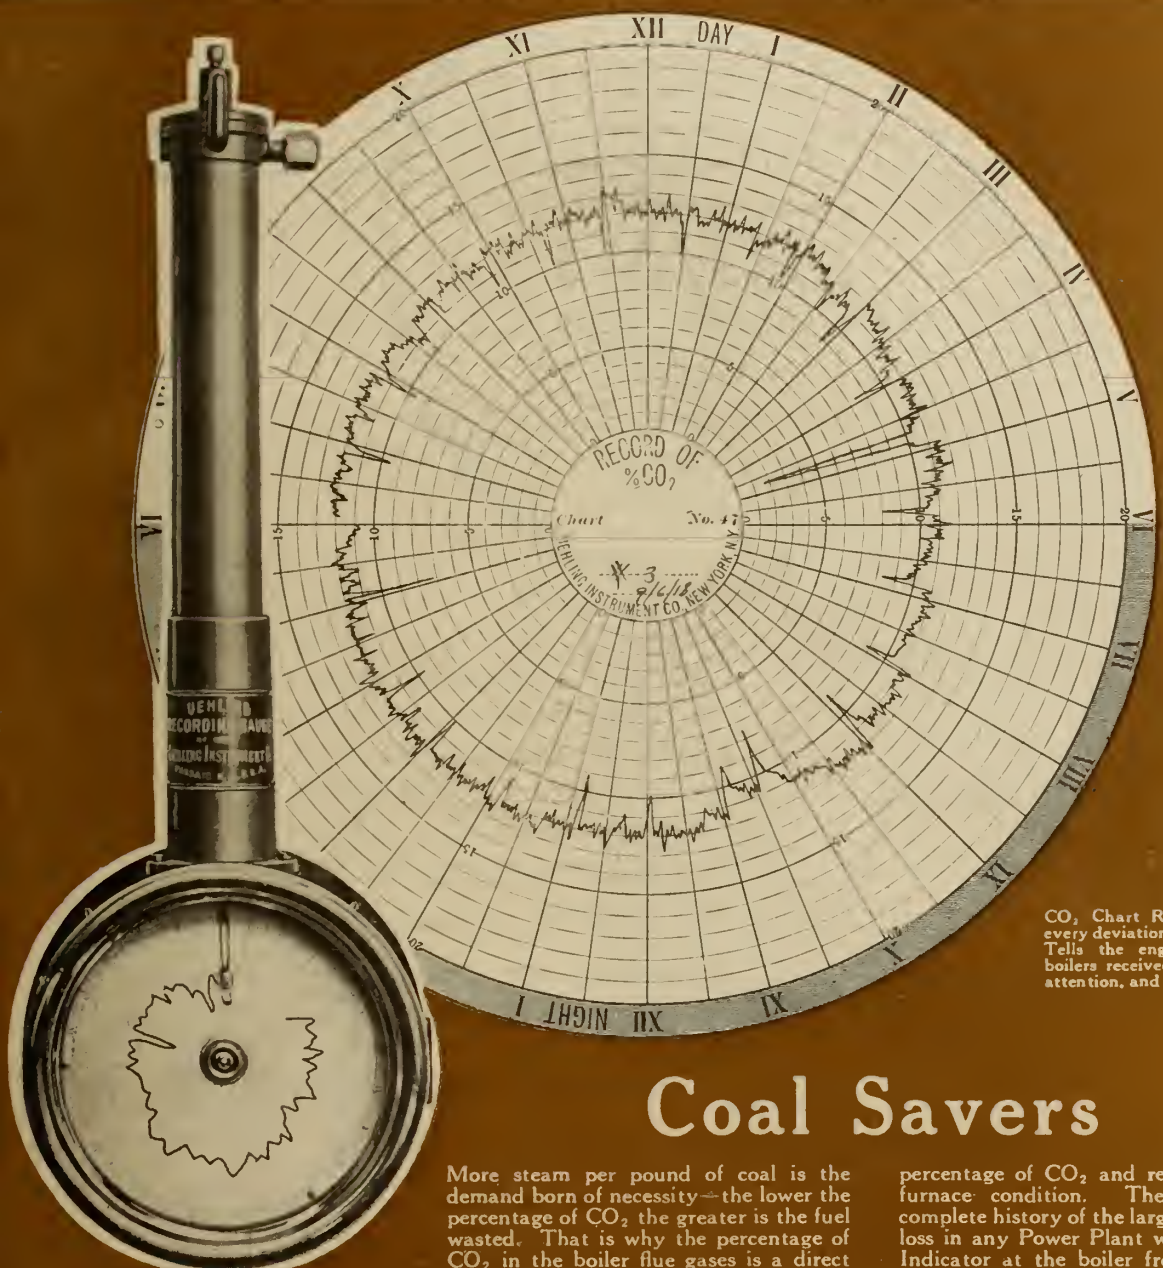
POWER HOUSE

A monthly newspaper devoted to the Generation, Transmission and Application of Steam, Gas, Electric, Air and Water Power; and to the operation of Refrigerating Machinery.

Published by The MacLean Publishing Company, Limited, 143-153 University Ave., Toronto

MONTREAL: Southam Bldg. LONDON, ENG.: 88 Fleet St., E.C. WINNIPEG: 1207 Union Trust Bldg

Vol. XII.—No. 1. Publication Office, Toronto—January, 1919 Published Monthly $1.00 per Year.



CO_2 Chart Record shows every deviation in economy. Tells the engineer which boilers received insufficient attention, and when.

CO_2 Recorder for Office of Chief Engineer. May be installed at any distance from the boilers and will trace continuous records of the changes in CO_2 and show these changes exactly as they occur during every second of operation.

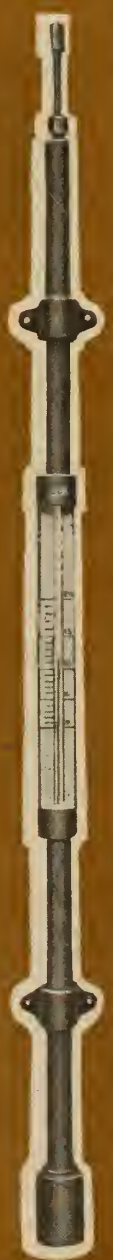
Coal Savers

More steam per pound of coal is the demand born of necessity—the lower the percentage of CO_2 the greater is the fuel wasted. That is why the percentage of CO_2 in the boiler flue gases is a direct indication of combustion economy.

Uehling CO_2 recorders furnish continuous (not intermittent) records of the percentage of CO_2 and reveal the true furnace condition. They provide a complete history of the largest individual loss in any Power Plant while the CO_2 Indicator at the boiler front holds the firemen responsible for the record produced.

Write for further details.

Uehling Instrument Co., 2018 Empire Bldg., New York City



CO_2 Indicator for mounting on the boiler fronts to guide the firemen. Shows the percentage of CO_2 and gives warning when improper furnace conditions prevail.

STEEL TANKS AND BINS

We have made a success of building steel plate work by specializing in it.

The new additions and improvements to our boiler shops have placed us in a better position than ever before to do this work right.

Our facilities in every department have materially increased. We have the equipment and the experience to turn out this special work as it should be.

If you are confronted with any problem on this work send it in and let our Engineers give you the value of their experience.

We design and build:

CONVEYORS
SMOKE BREECHINGS
STEEL STACKS
SPARK ARRESTORS
STEEL BUCKETS
ELEVATORS
RIVETED TANKS
STEEL TANKS
STORAGE BINS
COOKERS AND DIGESTORS
STEEL GAS MAINS
REFUSE BURNERS
WELDED TANKS
SETTLING TANKS

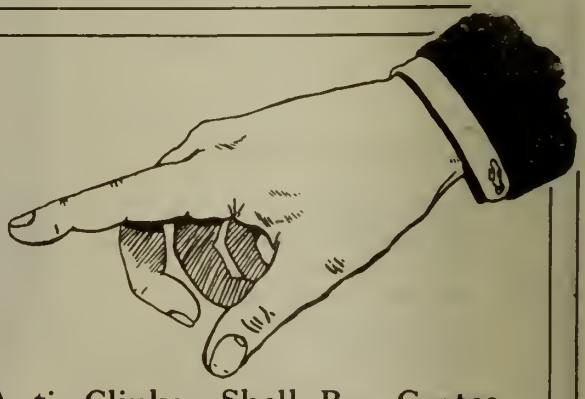
Clean Boiler Insurance



Boiler scale wastes tons of coal, makes disagreeable labor in being removed, causes shut-downs and a variety of other troubles. Are your boilers carrying scale? You can easily get rid of it. Get a barrel of

BOICO

It has a quick and certain action on all boiler scale. It loosens and brings down the hardest of old formations and keeps new scale from gathering—BOICO means Clean Boiler Insurance.

It will not carry over in the steam; it will not cause foaming or priming, and it is guaranteed not to injure packing or valves in the slightest. Write for Free Trial.

Anti-Clinker Shell Bar Grates

With these grates you can get more heat with less coal. They prevent clinker formation and maximum air space provides perfect combination. No wasted fuel where Anti-Clinker Shell Bar Grates are used.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

TIP-IT Patent Welding Process

gives you tools whose shanks are carbon and whose cutting tips are high-speed steel.

Shell-Bar Boico Supply, Ltd. 376 Dufferin Street Toronto

SPEED UP YOUR PLANT

CORRECT lubrication will do much to increase and maintain the efficiency of your plant. The right use of the proper lubricant means smooth-running and longer life for your power units, no matter whether you are producing ocean liners or baby carriages, electric power or metal ores.

Lubrication always has a direct and important relation to production costs. Correct lubrication means—

(a) Increased plant production.
(b) Lower operating costs.
(c) Minimum fuel consumption.
(d) Smaller repair bills.
(e) Longer life for your power equipment.

Correct lubrication requires not only high quality lubricants, but carefully selected lubricants. To correctly lubricate your plant, you must use the right lubricant for each specific purpose. Do not let poor lubricants or incorrect lubricants prematurely wear out expensive equipment.

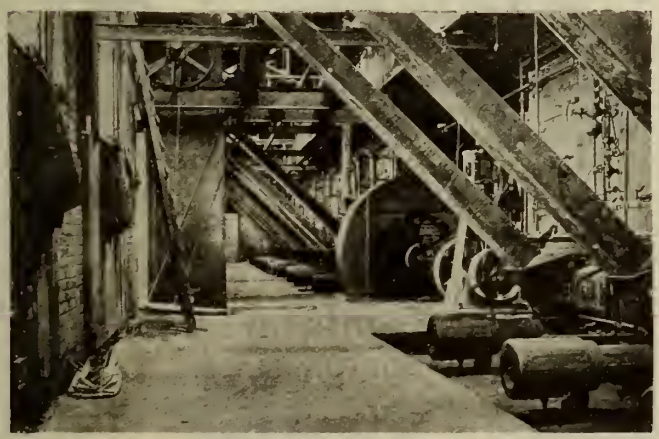
15 Tons of Coal FREE

Mr. Engineer, does a saving of 15 tons of coal in every 100 tons interest you? This is an immediate and permanent result that comes from the installation of the

JONES UNDERFEED STOKER

It also effects a big saving of labor, automatically maintains a uniform pressure, and responds instantly to load fluctuations. Everything that should be burned to generate steam is consumed—this means no fuel waste.
And there are many other advantages in using the Jones Automatic Stoker.



Serves day in and day out with very little attention.

Ask the user. We'll gladly put you in touch with some in your locality.

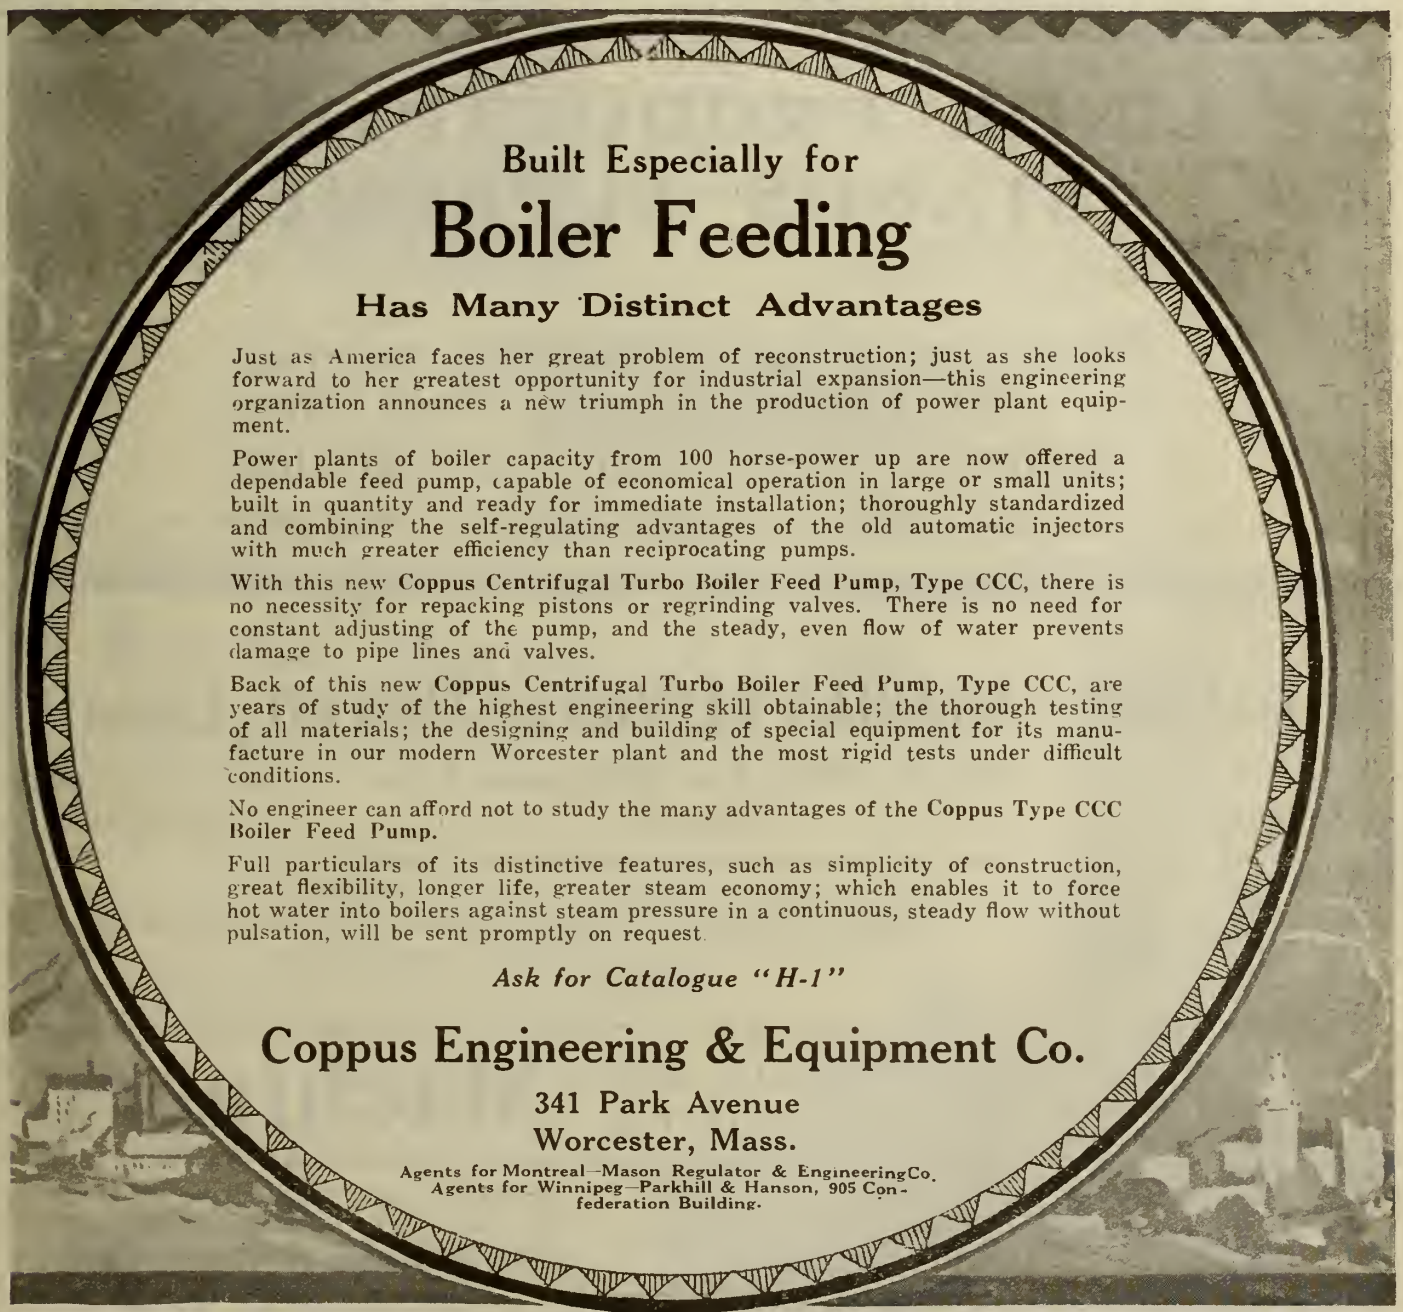
A New Triumph

In the Production of

Power Equipment



Built Especially for

Boiler Feeding

Has Many Distinct Advantages

Just as America faces her great problem of reconstruction; just as she looks forward to her greatest opportunity for industrial expansion—this engineering organization announces a new triumph in the production of power plant equipment.

Power plants of boiler capacity from 100 horse-power up are now offered a dependable feed pump, capable of economical operation in large or small units; built in quantity and ready for immediate installation; thoroughly standardized and combining the self-regulating advantages of the old automatic injectors with much greater efficiency than reciprocating pumps.

With this new **Coppus Centrifugal Turbo Boiler Feed Pump, Type CCC**, there is no necessity for repacking pistons or regrinding valves. There is no need for constant adjusting of the pump, and the steady, even flow of water prevents damage to pipe lines and valves.

Back of this new **Coppus Centrifugal Turbo Boiler Feed Pump, Type CCC**, are years of study of the highest engineering skill obtainable; the thorough testing of all materials; the designing and building of special equipment for its manufacture in our modern Worcester plant and the most rigid tests under difficult conditions.

No engineer can afford not to study the many advantages of the **Coppus Type CCC Boiler Feed Pump.**

Full particulars of its distinctive features, such as simplicity of construction, great flexibility, longer life, greater steam economy; which enables it to force hot water into boilers against steam pressure in a continuous, steady flow without pulsation, will be sent promptly on request.

For the Storage of Food

Nowadays, when we have to feed our allies as well as ourselves, it is doubly essential that all food in storage be kept as nearly perfect as possible. Any spoilage means a reduction in the available supply.

That's just one more good reason for using

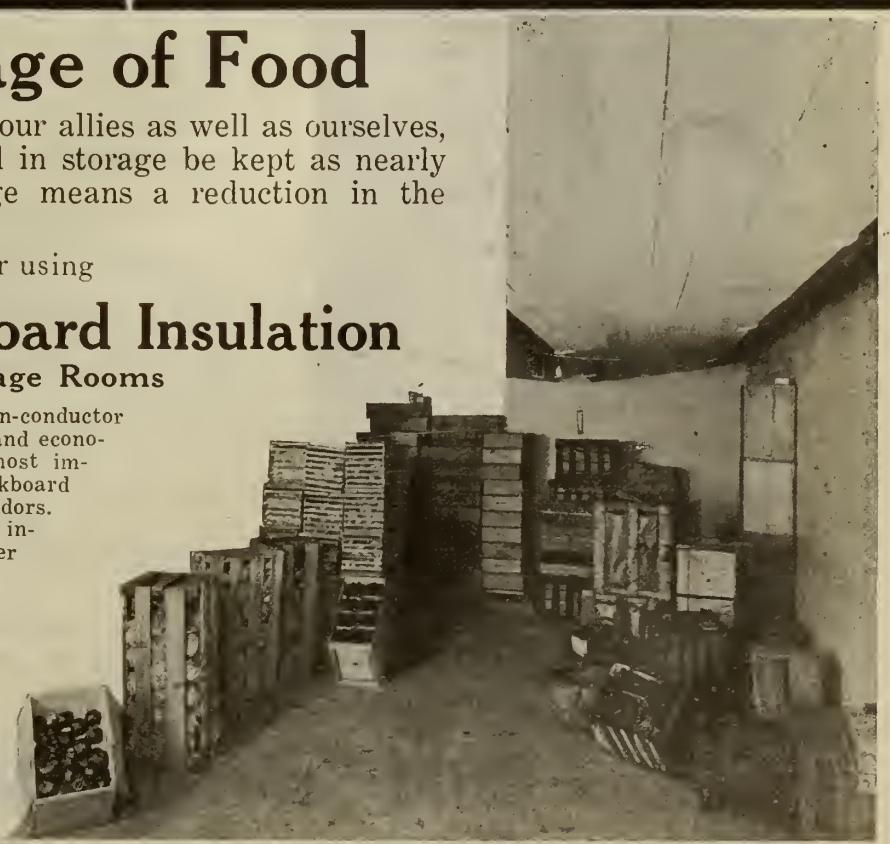
Nonpareil Corkboard Insulation

For Cold Storage Rooms

Because Nonpareil Corkboard is such a good non-conductor of heat, rooms insulated with it can be easily and economically held at the proper temperature—a most important point. Furthermore, Nonpareil Corkboard will not rot, mold or give off offensive odors. Properly erected, it is vermin-proof. Cork insulated rooms, with Portland cement plaster finish, are easily kept in sanitary and hygienic condition, reducing to a minimum the danger of contaminating the goods in storage.

If you are interested in the proper insulation of food storage rooms, write for a copy of the 152-page illustrated book. "Nonpareil Corkboard Insulation." It and a sample of Nonpareil Corkboard will be sent on request, without charge or obligation.

Armstrong Cork & Insulation Co.
504 McGill Building
Montreal, Quebec, Canada



A food storage room in the famous Battle Creek Sanitarium, Battle Creek, Mich., insulated with Nonpareil Corkboard.

A FAIR BARGAIN

It is unjust to charge too much for Refrigerating Machinery and poor business policy to charge too little. There is a point between where the buyer and seller must meet to conclude a fair bargain.

No transaction is ever entirely satisfactory that is not mutually beneficial. Goodwill never becomes an asset of any Manufacturer who charges too much for his product, and no Manufacturer can be successful who sells at less than a fair profit. Either the customer suffers or the firm sooner or later goes out of business. When you buy on the basis of price alone you generally pay for it and then some. Quality is remembered long after the price is forgotten.

If you are interested in Mechanical Refrigeration, we can furnish a plant to meet your local conditions at a fair price, all things considered.

The Quality and Service Guarantees back of all York Products should lead you to give us a chance at your business. Our interest in every plant after it is erected is a further protection to you and an assurance of our good intentions.

An inquiry from you will have our careful attention.

The Customer's Viewpoint

PRESENT and future customers can look upon the sales combination of the SANFORD RILEY STOKER COMPANY and the MURPHY IRON WORKS from the viewpoint of service.

While in a sense it is true that each Company will act independently, nevertheless, their *service* efforts will be *united into one constructive force* available from a greater number of strategic points.

This combined service is quite unlike all others. It is designed from the customer's point of view rather than from the builder's. This new service begins with the customer's needs—takes his conditions into consideration —and sees him through.

When in the market for stokers or when you wish advice on the operation of your present equipment, don't overlook the advantages of this new and enlarged service.

Since no two plant conditions are alike you will find it to your advantage to profit by the experience of our engineers. They will gladly analyze your plant conditions and prescribe the remedy. If you will drop a line to our nearest office they will help you to get the most out of your present equipment or suggest new equipment which will save you money, men, and fuel.

Two Mines with but a single thought

The coal mine and the asbestos mine have a big job in common—maximum production of power.

With the burning of coal in these times goes the obligation to use its heat efficiently. So every ton of fuel mined summons more asbestos from another mine, automatically, to guard jealously the heat from that fuel.

The two mines are racing together toward a common goal.

As the largest factor in the mining and fabrication of asbestos, Johns-Manville bears a burden of heavy responsibility. Asbestos is the fibrous mineral base of the most efficient heat insulations. It is the necessary other 15% in 85% Magnesia.

It is, as well, the basic material for many economical packings which reduce friction, prevent leakage, resist wear, and save power. In almost every plant improvement or extension, asbestos in one form or another is practically indispensable.

This development of asbestos from the status of a little known curiosity to its present rating as an industrial necessity, is due in no small part to Johns-Manville. So we can be doubly proud that when the nation needed Asbestos, our mines and factories, our laboratories and mills, our engineers and chemists, all were ready to play their part in the nation's service.

POWER HOUSE

Historical Development of the Steam Turbine-- III

The Third Installment of a Series Dealing With Development of the Turbine—Growth in Size of Turbo-Generator Units in Recent Years—Compounding Adopted With Marked Success

THERE has been a lot of misapprehension about turbine blading. With all types of turbines, the design and material of turbine blading have undergone some evolution. Of necessity, blading is subjected to very arduous conditions. It works in a steam current of considerable velocity, the steam often being laden with moisture and sometimes with chemicals, and solid foreign particles as the result of priming boilers. Centrifugal stresses must of course be properly considered, but far more important is the fact that any blading must be able to withstand the tendency to vibrate in the steam current.

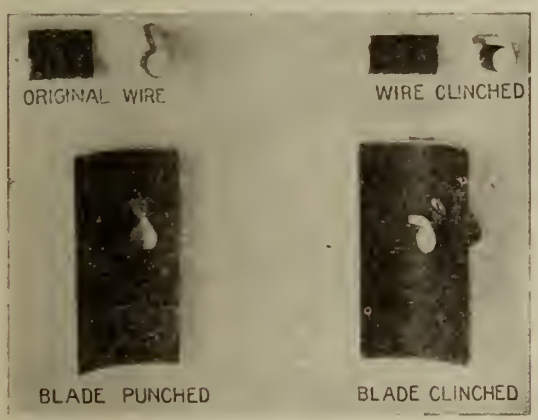

FIG. 27—COMMA WIRE TYPE OF BLADE LASHING.

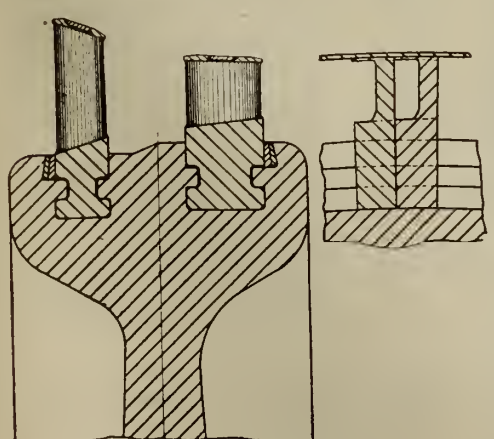

FIG. 28—TWO ROW BLADING.

The characters of the two salient types of turbine elements, impulse and re-action, require quite different blading; the one, massive blade sections, and the other, relatively light sections. However, the strain on the blades due to centrifugal force is the same in either case, and in the event of collision between blades the one is as subject to injury as the other, with the difference, however, that the results may be more far-reaching in the case of the more massive blades. In some early designs, breakages were due to contact between the stationary and revolving elements, resulting from distortion of theh cylinder structures. This has been eliminated by better design of these structures, the elimination of ribs and all unnecessary excrescences which might lead to internal strains in the castings or distortions due to uneven heating and cooling.

The principal cause of the breakage of turbine blades is vibration in the steam current. There are scarcely any records of blades having broken because of centrifugal force per se. Shrouding and other means of bracing the outer ends of turbine blades to each other have been employed to reduce the tendency to vibrate. Such devices increase the natural periodicity, and hence reduce the amplitude of vibration. Later designs of blading have their sections tapered, there being some 40 per cent. more cross-section at the foot than at the tip. With this construction, the deflection due to vibration will be distributed over a considerable length instead of being concentrated at the point of attachment. The later method of attaching re-action blades is shown in Fig. 26, the blades having a foot forged on the end which fits in a groove in the floor of the main groove of the blade-carrying element. The spacers between the blades are dovetailed to correspond with the dovetailing of the main groove, thus completely interlocking the blading and rendering the attachment at strong as the blades themselves. Large blades, like those shown, have their grooves provided with compound wedges which help to fill the grooves more completely. This type of blading was first employed in all commercial turbines in 1911, since which time little trouble has been experienced due to vibration of blades. This construction replaced the re-action blade system devised by Parsons in 1896 which comprised alternate blade and spacing pieces, each drawn to shape and cut to length, and calked in grooves very slightly dovetailed; the root portion of the blades being slightly serrated but friction, the result of calking, was wholly depended upon for securing the blades.

Ingenuity on the part of the builders of re-action turbines has not been lacking in suggesting improvements, but the apparently crude construction of Parsons was not easily to be improved upon, for it is still employed by builders of re-action turbines in Europe. The Fullager system was introduced in 1904, and was employed by the Allis-Chalmers Company in the United States and by William & Robinson in England. The Allis-Chalmers Company were compelled to abandon the riveted shroud portion of the Fullager system on account of a patent covering this, controlled by the General Electric Company. They

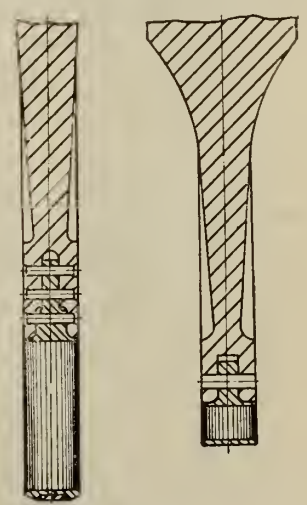

FIG. 29—SINGLE ROW BLADE CONSTRUCTION.

have since made further improvements to their construction.

BLADE LASHINGS

In the earlier machines, the blades were short and steam velocities low, so no blade lashings were required. Earliest blade lashings comprised a metal strip laid in a notch in the side of the blade, laced to the blades with fine wire and silver soldered. This method is still employed in Europe, except the lacing is discontinued and silver soldering relied upon entirely. The Westinghouse Company early abandoned this method and adopted in 1905 what is known as a "comma" wire construction,

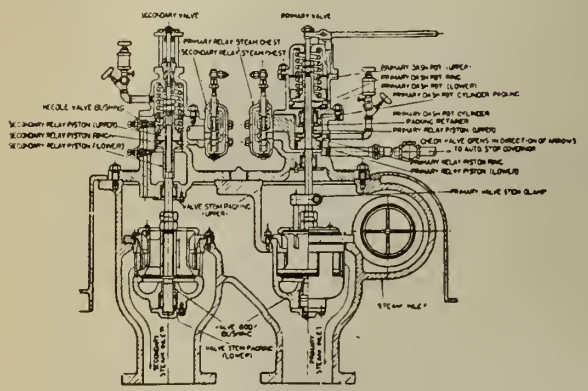

FIG. 30—CONTROL VALVE GEAR.

shown in Fig. 27; the tail of the comma being sheared at the walls of the blade and turned over between the blades, thus forming an abutment against the blades. This construction, while simple, was found after some years of use to be objectionable because of the close inspection required to insure a solid abutment, without which the blade may commence vibrating slightly between the abutments, the vibration increasing its amplitude on account of wear, until rupture is reached.

In the last few years silver soldering of the comma wire has been employed as an insurance and to avoid difficult inspection, the construction otherwise remaining the same. The clinching of the comma wire serves as a ready means of spacing the ends of the blade properly, after which the soldering may be performed. Brazing spelter was for a time employed in order to avoid the high cost of silver. It was found objectionable because the higher heat involved necessitated the blade cooling under some shrinkage stresses, through what appeared to be a critical temperature, sometimes causing rupture.

With later designs, involving large steam volumes at high velocities, the blade lashing is of paramount importance in order to reduce vibration in the steam current, and judgment must be employed in determining the length of segments to obtain the maximum rigidity on the one hand, and to provide the necessary flexibility for expansion on the other; it being remembered that the blading heats and cools at a different rate from the supporting drum or disc.

IMPULSE BLADING

As previously stated, impulse blades partake of a construction different from re-action blading. Generally they are more massive and the fourth wall to the blade passage, formed by a shroud, is always employed. Impulse elements were not employed commercially by the Westinghouse Company until the advent of their single-double-flow combination turbine in 1909. A number of different forms of impulse blade construction have been employed, not all of which are instructive. A modern standard construction of blading for two-row impulse elements is shown in Fig. 28. Two constructions of single row impulse element (Rateau turbine) are shown in Fig. 29. In each case the shroud is integral with the blade. A groove is cut in the shroud into which is inserted a strip of suitable length, which is brazed to the blade. The blade is drawn to the shape corresponding to the shrouded portion, the blade portion between the shroud and base parts being formed by a profiling milling operation.

BLADE MATERIALS

A brass alloy, known as Delta metal, was employed for re-action blades for the earliest machines in this country. Some blade breakages, which no doubt were due to vibration of the blades themselves, were attributed to defects of the material; such as crystallization, due to heating and cooling. Careful trial in a few machines showed us that blading made of ordinary steel would not corrode, so between 1904 and 1907, steel was adopted, and many of these machines are in operation to-day without showing any particular corrosion. However, enough cases of severe corrosion appeared to render the use of ordinary steel blading untenable.

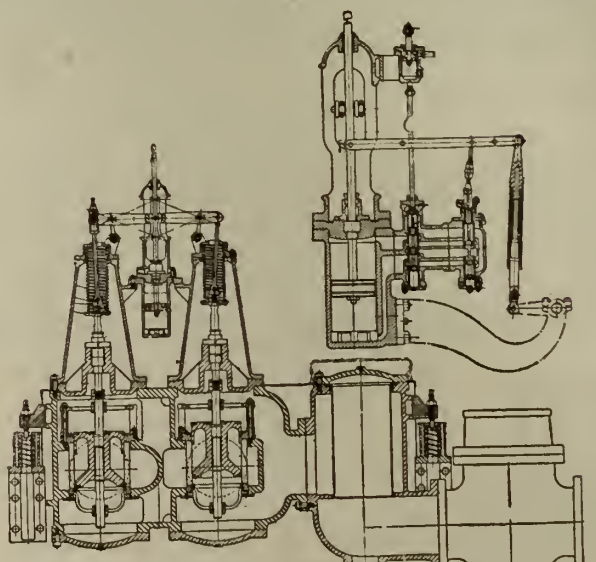

FIG. 31—A MODERN CONTROL VALVE AND ITS RELAY.

The effects were obviously caused by corrosion (not to be confused with erosion) and occurred mostly at the dew point, that is, at the zone of the turbine where, on account of latent heat being given up, superheat is lost and moisture commences to be precipitated. The cause of corrosion in power house apparatus seems obscure; it exists in one plant, and is absent in another, and the analytical chemist has not been of material assistance in determining specific causes. No doubt injudicious use of boiler compounds and the presence of unsatisfied oxygen with pure water were among the reasons.

In 1907 blades were made from Monnel metal, the original steel ingot having 25 per cent. of copper welded to the outside by a proprietary process, subsequent rolling and drawing still maintaining the proportion of copper in the final blade shape. While more resistant to corrosion they are by no means immune. So a bronze alloy was again adopted; this time using an alloy containing copper 97 to 98 per cent., tin 2 to 3 per cent., phosphor 0.03 to 0.07 per cent., which for moderate stresses is still employed. For higher stresses and impulse blading a low carbon steel is employed, having a carbon content not to exceed 0.08 per cent., combined with 5 per cent. nickel. This is practically a nickel iron, manufactured in an electric furnace.

The quality of material has always been considered as being a considerable factor in the ability of a blade to resist fracture under vibrating stresses. No doubt homogeneity is important, and some low carbon steel made by ordinary processes has failed for lack of it. It would appear that while the strength of a section under tension depends upon he taverage strength of the fibres, the ability to resist vibration is perhaps only dependent upon the strength of the weakest fibre.

A variety of materials have been suggested for blading, and employed at one time or other by various manufacturers; a few may be commented upon as follows:

NICKEL-STEEL, higher in both nickel and carbon than that mentioned above, is used in Europe, but alleged to be by no means immune from corrosion.

NICKEL-BRONZE (80-82) has been successfully employed by some manufacturers. It is alleged to become brittle by absorbing carbon monoxide should it be present in the steam.

MONEL METAL has satisfactory characteristics but it is difficult to work and varies in composition.

NICKEL, if pure, has satisfactory physical characteristics and is immune from corrosion.

GLANDS

In their early turbine work, the Westinghouse Company employed a steam labyrinth similar to that employed by

Parsons. It had the objection that to provide enough sealing steam to preclude air leakage invariably meant an objectionable leakage to the engine-room. In 1903 was developed the well known water gland which has been employed without material change until this time. It comprises simply a double centrifugal pump operating in a chamber. It is provided at its periphery with water, say of five pounds greater pressure than the pressure against which it is designed to pack; the pump thus maintains an annulus of water at the outer edge which forms a very complete seal.

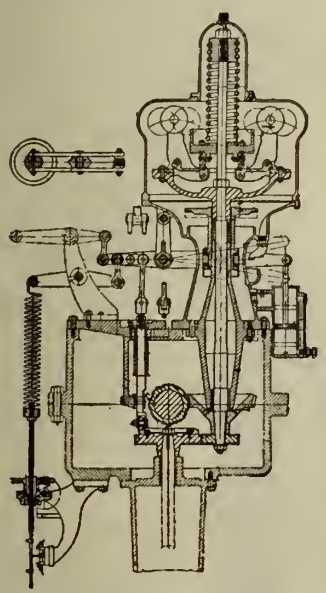

FIG. 32—GOVERNOR DETAIL.

The advent of water glands reduced a troublesome and difficult detail to one causing no concern to either the designer or the manufacturer. It is extremely simple in operation, requiring only a supply of water of the requisite pressure. This is best supplied by a float valve and tank located at the proper elevation. Inasmuch as there is some evaporation taking place in the gland, in part due to transfer of heat along the cylinder wall and to fluid friction of the fluid itself, water containing scale forming matter should not be used, so the gland is preferably supplied with condensate.

This type of gland has been extended to use with marine propelling machinery, in which case the gland must pack at any rotational speed in either direction, so a labyrinth pack is provided in combination with the water seal. Further the turbine governor is arranged to turn off the water supply and admit steam through a reducing valve to the labyrinth automatically, whenever the speed of the turbine is reduced below that at which the water gland can seal, usually about half speed. This is accomplished by providing the governor with two springs, one heavier than the other. The first half of the governor travel compresses the lighter spring at only about half full speed. The governor on reaching this position, operates a relay, turning steam on and water off, or vice-versa, according to whether the turbine is being accelerated or retarded. On the turbine reaching full speed, the governor will go to the outer half of its travel, compressing the heavier spring and controlling the main steam admission.

BEARINGS

The bearings devised by Parsons in 1890, comprising a shell surrounded by three concentric sleeves, are still employed for turbines that operate above their critical speed. Such turbines, however, are few in number, for so far as practicable, all modern machines operate below their critical speeds. For these, ordinary cast-iron bearing shells are employed, lined with babbit. The progress represented in them is that pressures per square inch of projected area have gone from 50 to 120 pounds and surface speeds from 50 to 80 or 90 feet per second, and it is believed that the duty to which such a bearing can be subjected is considerably beyond these limits.

An innovation introduced by the Westinghouse Company at the inception of their turbine work, was to provide the turbine bearing shells with four keys fitted in recesses on the outside. These keys have sheet metal liners beneath them, and are turned spherically to suit the housing which supports the bearing, the bearing being supported by the keys in the pedestal. Removal of liners from one side to the other provides a very definite adjustment of the rotor in the turbine cylinder. By these means the position of the rotor may be easily determined as well as definite knowledge of the least radial clearance obtained. The rotor may be displaced by definite amounts, and the rotor meantime revolved, permitting an adjustment of position to be made that beyond peradventure is what is required.

THRUST BEARING

The thrust bearing, comprising a number of collars, has been replaced by the Kingsbury thrust bearing which is capable of supporting an enormous thrust, enabling turbines to be constructed to have a considerable normal end thrust, and permitting the reduction of diameters of balancing pistons and the like. Furthermore, with such bearings an accurate balancing of the turbine, so that there shall be no end thrust, is no longer necessary. These thrust bearings operate satisfactorily with pressures as high as 500 pounds per square inch of actual bearing surface. They have been operated experimentally with pressures as high as 5,000 pounds per square inch without heating. Dr. Kingsbury has secured a variety of applications for his bearing for the main propeller thrust bearing; required, including heavy vertical generators. Most modern geared turbine steamers are being equipped with them for the main propeller thrust bearing; the multicollar type of marine thrust bearing, seven or eight feet long, being replaced by a single disc occupying an axial dimension of less than two feet.

GOVERNOR AND GOVERNOR VALVES

A speed-responsive centrifugal type of governor has always been employed in this country. A development of detail design has occurred which is of considerable interest, but would be of too great length to be described here. The result is the employment to-day of governors of large power and of such construction as to assure a perfectly constant rate of speed variation.

At the time the Westinghouse Company became a licensee of Parsons, it was Parsons' custom to control all machines by an electrical governor, comprising a solenoid actuating a steam relay. The solenoids were compounded and could be arranged to maintain substantially constant voltage, in which case the turbine operated at higher speed at full load than at friction load in accordance with the generator characteristics. Parsons was able to obtain excellent regulation from a solenoid, by introducing a constant oscillation to the lever system that connected the relay with the armature of the solenoid, effectively eliminating friction of rest. This also oscillated the relay, causing a quite violent opening and closing of the main valve and admitting the steam to the turbine in puffs. At that time

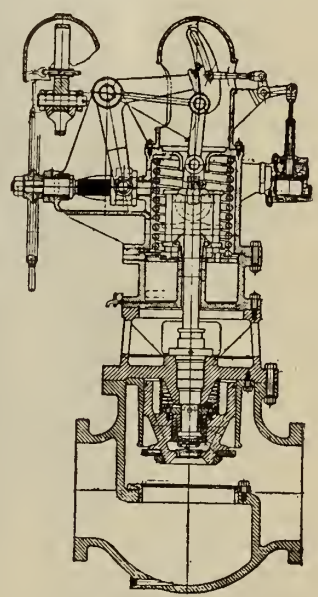

FIG. 33—TURBINE THROTTLE VALVE.

there were few cases in Europe where alternating-current generators operated in parallel, so the electrical governor was satisfactory.

The governor control employed by the Westinghouse Company in their earliest machines employed a similar steam relay, substituting a speed responsive fly-ball governor for the Parsons solenoid. The steam relay went through a process of elaboration and improvement. Arrangements were developed for the automatic operation of by-pass valves by the same system to enable the turbine to carry heavy overloads. An example of this valve gear is shown in Fig. 30.

The character and the quickness of

governing to be obtained with such mechanism left nothing to be desired. An objection to it was that its method of operation was not obvious to the observer, and the cause of any little derangement was not easily diagnosed. Later with the advent of larger machines, the puff system of admitting steam was found to cause at times objectionable re-action and vibration in the main steam lines of the power house, so that by 1909 the steam relay began to be abandoned for the well-known hydraulic relay and floating lever that is employed to-day, using oil at 50 pounds pressure provided by the regular turbine oiling system. At this time it was arranged that in cases of smaller turbines, where the steam flow was 20,000 pounds or less per hour, no steam relay would be employed, the regular governor being sufficiently powerful to operate the valves direct.

In the earlier machines, cast iron or ordinary bronze, double-heat, poppet valves were thought good enough. The higher superheats and larger capacities of to-day have brought about considerable changes in these parts. A high grade nickel bronze is employed for quite small sizes. Generally steel is employed for all parts, the seats in both the valve and cage being formed by monel metal rings suitably secured in place, the life of which appears indefinite. A modern control valve with its relay for a large turbine is shown in Fig. 31, and the design of the governor controlling it, Fig. 32.

Automatic Stop Governors

All machines except the earliest have been provided with automatic stops. There has been no particular change in these during the last ten years. In earlier machines it was thought preferable that the automatic stop governor that the automatic stop governor should operate a separate and distinct valve in the main steam line. This was found objectionable in some cases as the separate automatic valve would never be operated except in the emergency when, on account of long disuse, it may be found to be inoperative. It was therefore abandoned and the main throttle valve itself arranged to be operated automatically by the stop governor. The advantage of such an arrangement is: first, the valve must necessarily be maintained tight; second, of necessity it must be operated every time the turbine is started or stopped; and third, the valve may be partially closed even while the turbine is operating, so there may be assurance of no sticking in the pistons, etc. Fig. 33 represents a modern throttle valve of this type. The seats are of monel metal which appears to be the metal most capable of resisting the erosive action of steam.

13,200 2,300 575-VOLT MOLONEY TRANSFORMER, SINGLE PHASE, 1,500 KV-A. CAPACITY.

NEW DEVELOPMENT IN TRANSFORMER CASES

The accompanying illustration shows a new departure in the making of oil-tight transformer cases. As is well known to operating engineers, the usual type of case with the corrugations cast into the base is a constant source of trouble. In the case illustrated the Canadian Moloney Electric Co., Bank of Hamilton Building, Toronto, have produced an all steel arrangement which is absolutely oil tight. The bottom of sheet steel is cut to fit the corrugations of the case by the oxy-acetylene cutting torch and is then solidly welded to it by the same means. This ensures an absolutely oil-tight joint and no trouble is experienced through expansion troubles as the bottom and sides are of the same material and have the same co-efficient of expansion.

It will be noticed that a solid sub-base is provided. equipped with eyebolt for block and tackle wide wheels. By the use of wheels it is found possible to move the transformer, weighing fifteen tons, with the use of six men, no jacking or other work of like nature being required.

A quick opening gate valve, on the oil connection is provided, and a special oil-tight connection enables self-draining connections to be made on the transformer water cooling coils.

The transformer illustrated is being erected in the shop and is of 1,500 kva. capacity, three-phase, oil insulated, water cooled. The primary voltage is 13,200 and the secondary either 2,300 or 550. Three of these have been insulated at Leaside Munitions in Toronto.

The illustration gives an excellent idea of the coils method of bracing and the arrangement of the leads to the terminal board.

HOW TO SAVE COAL

Coal is the chief form of fuel used in the generation of steam, though wood is still available in some sections, particularly in connection with saw mills. Oil and natural gas are used where they can be had at a cost that is not prohibitive, and the gases from blast furnaces are used to a considerable extent in the iron regions. Waste and refuse of many kinds are likewise burned with success for steam generation, though special furnaces are usually required, adapted to each particular kind of fuel. Coal being by far the commonest fuel, it will be assumed to be used, throughout the following pages, except where the contrary is expressly indicated.

In general, it is more economical to burn soft coal than hard, though this will vary somewhat with the locality, and also with the nature of the output of the plant. In some cases freedom from smoke is the determining factor, etiher because of local ordinances against smoke, or because smoke or some of the other volatile substances that are given off by soft coal would be detrimental to the product that is manufactured. In this latter case "economy" has to be construed in its broadest sense, as including the operation of the plant as a whole.

The Power Plant of the Simpson Knitting Mills

A Power Plant Where Isolated Plant and Control Station Service Combine to Give Economy in Operation — Large Amount of Steam is Used For Industrial Plant Purposes

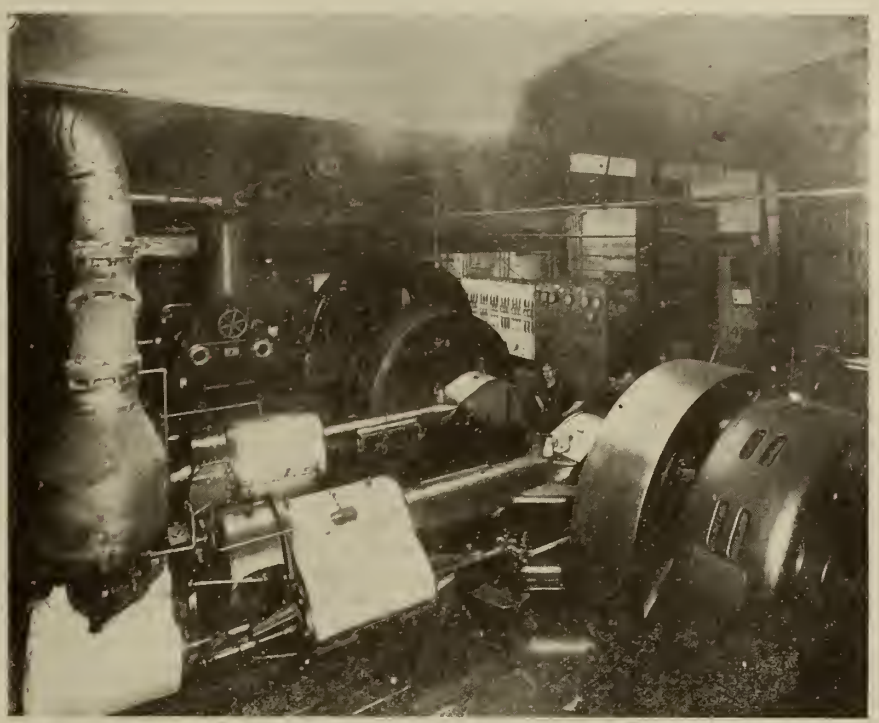
By HUGH CLARK, Chief Engineer

THE power plant of the Simpson Knitting Mills, Toronto, has been in continuous operation night and day for the past ten years, and since the commencement of the war, now happily past, the firm has supplied war material for every one of the Allied Governments and has succeeded in maintaining its domestic trade as well as filling with promptness the requirements of the Allies.

Boiler Room

Five horizontal return tubular boilers are installed. These boilers are 72 in. by 18 ft. and are fitted with 72 four-inch tubes. Three of these are of Goldie and McCulloch make and the remaining two are of John Inglis make. In addition to these boilers there is also installed one 400 hp. Robb Brady Scotch boiler.

The boilers are fed from an open Webster feed-water heater by a 10x7x12 outside packed Martin duplex pump, with a similar pump in reserve. The feed-water is heated to 200° Fah. with the exhaust from the engines, and the heater also receives the returns from the heating system. These latter are brought back through a Martin 6 x 10 x 12 Martin vacuum pump.



VIEW OF ENGINE ROOM

The plant requires a considerable amount of hot water for dying, washing and scouring the wool used. This water is heated in two closed heaters, also heated by exhaust steam and the process water is delivered at a high temperature, making for greater efficiency and economy in manufacturing.

Exhaust steam is also used for drying the raw stock after washing, and also for drying the finished fabric.

A hydraulic power pump is also used for humidifying the atmosphere, a very essential factor in the carding and spinning of cotton yarns.

Engine Room

The main engine room is set entirely apart from the boiler room and the units consist of three distinct sets. The largest unit is a Robb Armstrong 28x39x30 cross compound non-condensing engine running at 120 revs. per min. This engine is direct connected to a Swedish General Electric three phase, sixty cycle, 600 volt alternator. The other two sets consist of two 16x26x18 Goldie and McCulloch tandem compound non-condensing engines running at 200 revs. per min. and direct connected to 250 k.w. 8 sixty-cycle alternators; also generating current at 600 volts, three phase. These generators are of Canadian General Electric make.

The generators are excited from a 20 k.w. 125 volt d.c. Swedish General Electric generator, driven by an eight by eight Robb Armstrong vertical engine, running at 400 revs. per min., direct connected to the generator.

A motor generator set is used as an auxiliary source of excitation. This unit is of Swedish General Electric make and consists of a 25 k.w. 125 volt d.c. generator driven by a 600 volt, 1,150 rev. per min., 40 h.p. induction motor.

The main generators are run in parallel, synchronizing being done by means of lamps.

Central Station Energy Used

At present 75 per cent. of the power is taken from the Toronto Electric Light Co. From four to 7 p.m. the large unit is used and carries the load during the Central Station peak. A transformer house also forms part of the equipment, six 100 k.w. transformers stepping the primary voltage of 4,000 down to 600.

Switchboard

The main switchboard consists of five white marble panels, three ft. by seven in size. The switching equipment consists of eight 200 amp., double pole, three pole switches, and two 400 amp. switches of similar type. Each circuit is also fitted with a three-pole Swedish General Electric oil switch. All circuits are metered by Terranti ammeters.

The Central Station busbars are on top and the company's own on the bottom, and ease and flexibility in operation are obtained by the excellent design of the board. There are five machine panels, all fitted with the latest operating devices, such as inverse time element relays, circuit breakers, ammeters, voltmeters, and a recording voltmeter.

BUYING COAL IS A SCIENCE

The best method of buying coal will vary with the quantity that is used. In small plants the cost of making frequent analyses and tests is usually prohibitive, and in such cases the buyer must be guided by general considerations, rather than by an accurate knowledge of the heating value of the fuel. He should see that the coal has been freshly mined, and that it comes from mines which yield a uniform and satisfactory product, as judged by his own experience or by that of others. It is better, in general, to be content with a supply of known and proved worth, rather than to experiment on any large scale with untried mines or sources. Experimenting in a small way may be encouraged, however, if the results are checked up by actual steaming tests, so that positive and reliable information is obtained, for future guidance. It is safest for the small buyer to deal with a merchant who has a good reputation to maintain, even though the first cost of the fuel is a little higher.

Systems of Hot Water Heating Explained

Gravity System Principles of Action and Causes of Failure—Proportioning and Layout of Installation—Honeywell System—Forced Circulation System—Advantages of Hot Water Heating Over Steam

By S. BALMFIRTH

WATER in motion is the best medium for absorbing heat, transmitting same to required points and there delivering. Still water is a poor absorbent, but in circulation absorbs heat rapidly. Having high specific heat or absorbing capacity, it lends itself readily to man's use for heating, so that in most buildings of any considerable size hot water is becoming the favorite method of heating.

Systems

Gravity open
Gravity closed
these are not controlled. Honeywell or circulation booster, forced circulation systems.

The first system consists of one boiler, piping, radiators and expansion tank. In this system the water is heated in the boiler, which is placed in the basement of the building and circulates through the piping to the radiators where it delivers up its heat and flows back to the boiler again. This sounds quite simple and so it is, but it might pay us to investigate a little and find out why and how this is done.

Gravity System

We will assume a gravity system of open type, in a house of, say, two storeys and basement, giving a total height of about twenty-five feet. Water weighs approximately 62.5 lbs. per cubic foot, so that for every foot in height we have a pressure of 62.5÷144=.434 lbs. per sq. in., so that at the lowest point in our system, we have a pressure of .434× 25=10.85 lbs. per sq. in. with water at its greatest density, that is, 39 deg. F. However, for conveniences, we will assume the water to be at ordinary temperature, say 50 deg. F. We will further assume that the system is filled, air all out of the radiators, and all ready for starting up. Now, if the fire be lighted, a change of conditions takes place. The water in the boiler is heated and at once expands, taking up more space, therefore becoming lighter in weight, volume for volume. At 150 deg. F. water weighs 61.18 lbs. per cubic foot, a reduction in weight of 1.23 lbs. from its original weight, at 50 deg. F. This gives a pressure per square inch of .425 lbs., very nearly, per foot in height. Now, if we could imagine that no water from the return side of the heating system were admitted to the boiler. and also that the water in the boiler and flow risers was heated, right up to the top to temperature already given, 150 deg., we should have a difference in pressure of (.434—.425) x 25 = .225 lbs. per sq. in.

Assume now that the water from the return side be admitted to the boiler, then we should have two columns of water of different weights with a common base. Naturally this cannot be, as we know. Water will flow in from the return side of the system because that side is the heavier, and the heated water will flow into the radiators, giving up its heat, down the return side to the boiler, where it is reheated and starts on the same cycle again.

Causes of Faulty Action

This illustration will give us not only the why of hot water heating, but also the why not, for it also discloses the reason that so many hot water installations are not the successes that they deserve to be. The figures given show that for a height of 25 ft. and a difference in temperature of 100 deg., we have a difference in pressure of only .225 lb. per sq. in., less than ¼ of 1-lb., and when we consider that 20 deg. to 25 deg. difference is all that is allowed between flow and return temperature in hot water heating systems, which gives a pressure of only .065 lbs. per sq. in., we can see that it is necessary to be very careful in the lay-out of a hot water system if it is to work efficiently and economically.

Proportioning

I do not intend or expect to show anything new or startling, or even original, but propose just to see what it is necessary to consider in the lay-out of a good hot water job. First, a properly prepared plan.

By a properly prepared plan, I mean one in which everything appertaining to the job has been figured out. The ground floor plan should be drawn to scale, and the risers marked in on it with the footage they are to supply, and the style of connection between main and branch. Also the amount of radiation should be calculated, not put in by guess, or cubical contents method, or any old rule of thumb, but scientifically (that much abused word) by the heat loss method. This rule takes into consideration the amount of fresh air required in each room, as well as the exposed area of wall and glass. This is the rule:

Add results obtained and divided by 160 for sq. ft. of direct hot water radiation required. Add results and divide by 250 for steam. Secondly, a properly proportioned boiler, well set up and having ample draft. When I say properly proportioned, I mean a boiler which has sufficient heating surface for the work it has to do, yet at the same time not so large that the circulation through it will be sluggish, or that the fire will require to be checked down all the time, nor yet so small that it is necessary to keep all drafts wide open in order to get the work out of it.

When we consider that out of the 12,000 or so B.t.u. in every pound of anthracite coal, only 8,000 are available for useful work, the rest being lost in radiation, leakages, producing draft and other boiler losses, it becomes obvious that too much care cannot be bestowed upon the selection and installation of the boiler. There are any number of good makes of boilers for this purpose. so that the matter of selection is fairly easy, but here are some of the requirements for a good boiler:

1st. It should be built of few parts.

2nd. It should permit of easy cleaning.

3rd. The sections should be fairly thin, so that the boiler does not hold too much water.

4th. The fire pot should be not less than eight inches deep.

5th. The grates should be, of course. shaking grates, but should be in two or more sections, if at all possible in the size of boiler.

6th. The boiler should be installed where there is sufficient room for a man to get around it, not down in a pit where the attendant has to jump down two or three feet every time he has to clean fires. Further, as far as possible. the boiler should be installed as nearly equi-distant from the risers as possible. and as close to the chimney as possible to avoid a long fule.

These requirements may or may not be obtainable in one boiler or installation, but they are the main points. Having obtained the boiler and seen to its proper installation, the next thing to do

For ½ air change per hour multiply.....	20	10	½	—10	—20	Outside temperatures	
cubic contents by	.5	.6	.7	.8	.9	"	"
" 1 air change per hour	1.0	1.2	1.4	1.6	1.8	"	"
" 1½ air change per hour	1.5	1.8	2.1	2.4	2.7	"	"
" 2 air changes per hour	2.0	2.4	2.8	3.2	3.6	"	"
Multiply exposed glass by	50.	65.	75.	85.	95.	"	"
Multiply exposed wall by	17.	20.	25.	27.	30.	"	"

Use co-efficient for ½ air change for rooms only requiring tempering.
Use co-efficient for 1 air change for bedrooms.
Use co-efficient for 1½ air changes for living rooms.
Use co-efficient for 2 air changes for halls, bath and exposed rooms.

is to lay in the mains. Right here is a splendid chance to make or mar the whole system. I have one building in my care which it is impossible to heat, through wrong design, although the boiler is amply large. The sizes of the mains are, of course, decided by the amount of radiation they are to serve. The following sizes of mains are taken from Kent's Handbook:

CAPACITY OF MAINS 100 FEET LONG

Inches.	Two Pipes Feet.	One Pipe Feet.
1¼	75	45
1½	107	65
2	200	121
2½	314	190
3	540	328
3½	780	474
4	1,060	645
5	1,860	1,135
6	2,960	1,800
7	4,280	2,700
8	5,850	3,500

Capacity of mains 100 ft. long expressed in the number of square feet of hot water radiating surface they will supply, the radiators being placed in rooms at 70° and 20° drop assumed. There is a danger of making the mains and risers too large and thereby checking the circulation. It must be remembered that the larger the mains, the greater will be the amount of water contained, and as this water is to be heated, it naturally follows that the circulation will be sluggish, and as the success of a hot water system depends upon the rapidity of its circulation, it will be seen that this is a most important point.

One small detail I might mention here is, to have all pipe ends reamed out clean, as a burr on a pipe reduces the area of cross section by fully 25 per cent. in the smaller sizes and also gives rise to small eddies, all of which tend to impede the circulation. All mains, both flow and return, should have a rise from the boiler of not less than 1 in. in 10 ft. The next point to watch is the way the branches are connected to the mains. Anyone who has watched a gravity hot water system at work from the time of its lighting up, will remember that the hot water flows along the the top of the pipe, that is, the top of pipe always gets hot first. So a little reasoning will show that if the first branch off the main be connected at the top, it will get the hottest water, and the other branches will naturally have a poorer circulation.

To avoid short-circuiting of the nearest radiators, therefore, with the natural result of robbing the further ones, it will be necessary to arrange to introduce friction into the circuits of the nearest, or rather to equalize all the circuits so that short-circuiting shall not take place. The ideal system is one in which the circulation to all radiators is equal, thereby ensuring water equally hot, and as it is obviously impossible to have the boiler equi-distant from all radiators or even to have all the mains and branches carry the same amount of radiation, some means of balancing the friction on the different mains and branches must be considered.

Assuming 4 branches on 2 mains; the first branch from the boiler should be made, generally speaking, with a tee turned down at an angle of 45 deg. and nipple and tee at the bottom plugged for cleaning, and then with a nipple in the tee and a 45 deg. ell, we have the first branch. The second branch should be taken off horizontally, the third with a tee turned up at an angle of 45 deg. and the last turned directly up from the main. If the amount of radiation does not call for a main of over 2 in. at the boiler, it should not be reduced below 1¼ in. at the end of the main. It may be necessary to vent the mains at different points.

To avoid short-circuiting of the system, the ground floor radiators should have a separate return main, which should enter the return header close to the boiler. If this is not done, the radiators on the ground floor will not heat properly, because the circulation will be held up by the cooler water from the other radiators. When making connections for the ground floor radiators off the risers, it is better to use O. S. tees or to use a connection like sketch. This will prevent the radiators on the upper floors from robbing those on the ground floor.

Expansion Tank

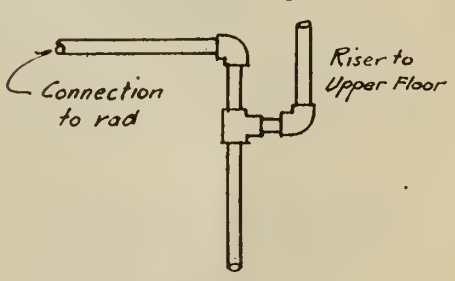
The expansion tank is, as its name implies, installed to take care of the expansion of the water. As water expands about 1-23 of its volume, from 50 deg. F. to 185 deg. F., it will be seen that a tank whose volume is 1-20 of that of the water in the system will be about right. This will take care of all expansion, and having ample room, will avoid the necessity of adding fresh water to the system due to boiling over. Most expansion tanks are too small, thereby causing an unnecessary expense in the operation of the system. For if the tank be too small, the system filled with cold water with the water showing in the gauge glass, then as the water is heated, the tank will overflow, carrying away heat. Now, as the outside temperature varies considerably, so must the temperature of the water vary. If the water has overflowed to any extent while the system was very hot, then cold water must be added to make up the loss, as the system cools off and as this fresh water must be heated it will readily be seen that with our varying temperature, that quite an appreciable heat loss will take place.

Radiators, in order to give off the maximum amount of heat, should be placed either under the windows if it be at all possible, but at any rate, next the outside wall. There is a difference of fully 25 per cent. in the efficiency of a radiator due to its position.

The Closed Gravity system differs only in that it has no expansion tank, but is supplied with a relief valve instead. The relief valve may be an ordinary lever and weight, or spring loaded valve, or the whole system may be connected to the city water system, in which case the pressure in the city mains acts as a relief valve. There is one advantage of a system of this kind over the open type, which I will take up later.

Honeywell System

The Honeywell system of hot water heating differs from both the open and closed gravity systems. In this system there is employed a so-called generator. This is entirely a misnomer, as the apparatus does not generate anything, but applies a varying pressure up to 10 lbs. on the flow side of the system. This results in a higher temperature being obtainable and also a more rapid circulation. Perhaps at first sight this may not seem feasible, but if the action be traced, it will be found that it is so. The usual maximum temperature for a



RADIATOR CONNECTION.

hot water system to work at is 180 deg. F., but generally the temperature is around 160° F. If the water in the boiler is not allowed to expand and rise in the expansion tank in the usual manner, the energy imparted to it by the burning coal must find an outlet somewhere, and this outlet can only be through the system of piping and radiators provided. With the Honeywell system a temperature equal to a steam pressure of 10 lbs. is possible, so that a higher temperature is possible at the radiators, and as none of the motive force is lost in the expansion tank, there is a very rapid circulation produced. Further, a greater drop in temperature between flow and return sides of the system may be allowed, which in turn increases the circulation. Where the gravity system has an effective range of temperature of only about 40 to 60 deg. F. that is from 120 to 180 deg. F., the Honeywell system has a range of from 90 to 240 deg. F This tends towards the use of smaller mains and radiators; 20 per cent. smaller than for gravity systems.

I applied one of the generators to the heating system that I mentioned before with the result that now the radiators can be heated, where as previously they could only be warmed, and this without any alteration to the system, or without using any more coal. But I would recommend all present to get the Honeywell book; it will repay any engineer for the time spent in its study.

Forced Circulation System

The last system I wish to deal with is the forced circulation system. To my mind this is the best system of heating, not excepting steam. In this system the circulation does not depend on the temperature of the water. The water is circulated through the radiators by means of a pump. The radiators are proportioned at the same rating as for steam, whilst the sizes of the mains and risers are calculated wholly upon the friction load on the pipe. In this system it is quite easy to make a one-pipe job, which works very well indeed. By running the mains to the top of the building and there branching off to the different drop risers and using O. S. fittings, it is possible to do with only one riser. By using this system there is no trouble with ground floor radiation or short-circuiting of any section. Further, the initial cost is lower than that of a steam system and the maintenance cost is much lower. I am operating one forced circulation system that I connected myself. I replaced three No. 9 Spencer boilers, using a No. 13 Sims heater and a three inch Mather & Platt centrifugal pump. There are 8,000 feet of radiation on that system. It takes about 100 Imperial gallons per minute at a temperature of from 110 deg. Fahr. for an outside temperature of 50 deg. Fahr. to 210 deg. Fahr. for an outside temperature of 20 deg. Fahr. This system does not give one day's work in the season. There are no valves to pack—I mean they never need packing because they are never used. There is no question of overheating or underheating, no radiators not heating because the trap has stuck. The friction head at the pump is 10 pounds, and the horse-power of the motor is 3 h.p. The temperatures are read hourly, and any corrections in the flow temperatures are made.

To sum up, in my opinion a hot water heating system is much to be preferred to a steam system for the following reasons:

There is a greater flexibility, or rather a longer range of temperatures through which the temperature of heating fluid may vary.

With a low pressure steam the range is extremely small, from 212 to 230 deg.

With a vacuum system the range is 140 deg. to 212 deg.

With a gravity system the range is from 120 deg. to 160 deg. Fahr.

With a closed system the range is from about 120 deg. to 230 deg. or even higher, depending on the pressure at which the relief valve is set.

With a forced circulation system the range is from anything desired to a temperature corresponding to the steam pressure with which the heater is supplied. I have frequently supplied water at 230 degrees.

With a Honeywell system the range is from 90 deg. Fahr. to 230 deg. Fahr.

Owing to the greater flexibility of hot water systems, they tend to the more economical use of fuel; as to the case of temperature regulation there is less probability of heating so much of the wide, wide, world, which often happens with a steam system on account of the usual perverseness of the average human, who would rather fling a window wide open in zero weather than attempt to regulate the temperature of the room he is in by using the radiator supply valve in conjunction with a little gray matter.

Further, there being no radiator traps there is less work for the man in charge, and no sticking of traps to stop radiators from working.

Refrigeration Troubles and Their Remedies

Corrosion, One of the Most Active Sources of Trouble—Tests for Acidity—For Ammonia Leaks and for Purity of Ammonia—Common Causes of Ammonia Leakage and Its Remedy

By JAMES F. PATTON

IN ALL refrigerating plants, corrosion of pipes, coils, and condenser tubes must be guarded against as it causes many troublesome problems and may seriously reduce the efficiency of the entire system. Oxygen, the active agent in the air, may soon become entrained in the water and cause considerable corrosion through its oxydizing power gradually attacking the iron with which it comes in contact. Water at 68 deg. Fahr. will absorb about 3 per cent. of its bulk of oxygen, while at 32 deg. Fahr. it will absorb 4.9 per cent. Oxygen is an extremely active element and serious trouble may result if proper precautions are not taken. Free acids may get into the boiler and decomposition of mineral salts may cause acidity of the boiler water. In general, corrosion is caused by impure or contaminated water or faults in the individual system. To prevent corrosion from air, the pumps and other parts of the system, especially these which have stuffing boxes, should be very carefully examined at frequent intervals, and in designing the piping system care must be taken to obviate all high spots, as air will accumulate at such points and cause trouble. The system must be kept full of water or brine, or the spaces above the liquid will surely fill with air. When the boiler feed water is heated to a high temperature the air will be liberated, and to reduce corrosion from this source an open type heater is to be recommended.

If a purge valve is located on the system it should be opened whenever air or foreign gases are suspected. When the condenser is stopped and fully cooled, open the valve and carry a small rubber hose to a pail of water, as shown in Figure 1. The bubbles which result show air or gas, but not ammonia, which will be absorbed by the water. If ammonia is discharged the temperature of the water will increase owing to chemical action. The evaporating pressure should never be brought below atmospheric pressure, which is zero on the gauge, because at such times if there is the least leakage air is sure to enter. If it becomes necessary to reduce the pressure below this point tighten the compressor stuffing boxes and permit the pressure to be low for the shortest possible time.

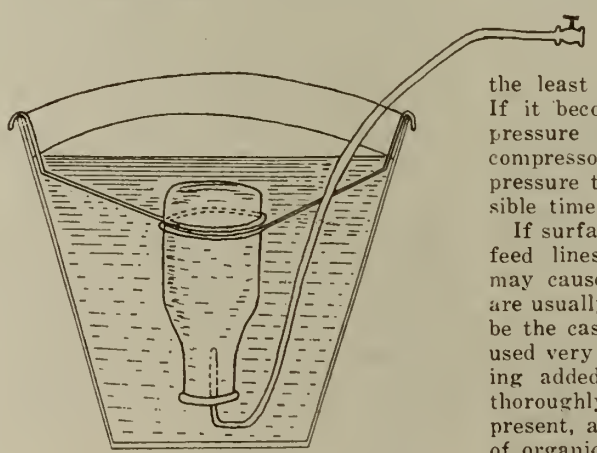


FIG. 1

If surface water is used in boilers and feed lines, sulphuric or carbonic acid may cause trouble, as these free acids are usually found in such water. If such be the case, sodium carbonate should be used very freely, a sufficient amount being added to the water to make it thoroughly alkaline. When sewage is present, acids due to the decomposition of organic matter may be expected, and when subjected to heat these are especially troublesome. The practical method of eliminating them is by agitation of the water in an open heater before it enters the system. This method, with the use of sodium carbonate, will usually produce good results. When high boiler pressures and temperatures are carried

there may be decomposition of the mineral salts in the water which may form hydrochloric and sulphuric acids. Magnesium chloride, if heated sufficiently, will liberate hydrochloric acid, but if the water is sufficiently alkaline to counteract this no trouble will result; if not, the remedy is in the use of sodium carbonate. Frequent water tests should be made to determine the presence of acids as water from a presumably reliable source may change without notice, due to the supply becoming contaminated. An approximate method of testing is to observe the color of the water in the gauge glass. Water which is transparent, or which is of a gray or straw color is usable, but a red discoloration denotes corrosion, which may be neutralized by lime or soda. A bright nail hung in the water will not rust if the water is sufficiently alkaline. These tests should not be accepted as final, but in every case where the water is suspected exact chemical tests should be made. A good test is to put a few drops of methyl-orange in a sample of water. This will give it a yellow color so long as the water is alkaline, but if the water turns pink it shows that acid is present. If red litmus paper is put in the water and does not turn blue, the water is not alkaline. If blue paper is tried and fails to turn red it shows the water is not acid. An accurate test for carbonic acid is the use of lime water, and if this acid is present the mixture will turn milky, while hydrochloric acid will turn it clear again. In some cases poor work in the manufacture of tubes causes corrosion. When a condenser tube is made of copper and zinc it frequently happens that these metals are not thoroughly mixed, and it is well known that these, if properly brought together with an electrolyte, galvanic action will be set up. An eating away of the metal in many systems has been traced to this action. the strong brine acting as an electrolyte. Trouble will also occur if water gets into the ammonia charge. Capacity will fall off, stuffing boxes will leak or run hot, and the only remedy is to eliminate the ammonia, then recharge.

Ammonia Leakage

Ammonia leakage is a frequent cause of trouble in every absorption machine. The efficient engineer is constantly on the lookout for these leaks, for while one leak may not be serious, several, if left uncared for indefinitely may seriously impair the efficiency of the system. The small ones should be located and repaired, and better still, the joints which might develop a leak should be watched. Naturally the oftener a machine is started and stopped the more likely it will be to develop leaky joints; also, a joint which may be tight when the machine is in operation and hot, may leak when it is cold. For this reason intermittent operation should be avoided if possible. Particular attention should be paid to the stuffing boxes in generator and exchanger as these are subject to great variation in temperature. When tightening, care should be exercised not to put on any undue pressure as extreme pressure on packing shortens its life. A worn rod in the piston stuffing box on the ammonia pump may also cause much trouble. This is easily located, but the trouble comes gradually, and the engineer may be deceived as to its condition till serious developments occur. A worn rod should not be tolerated, for in addition to loss of ammonia it also

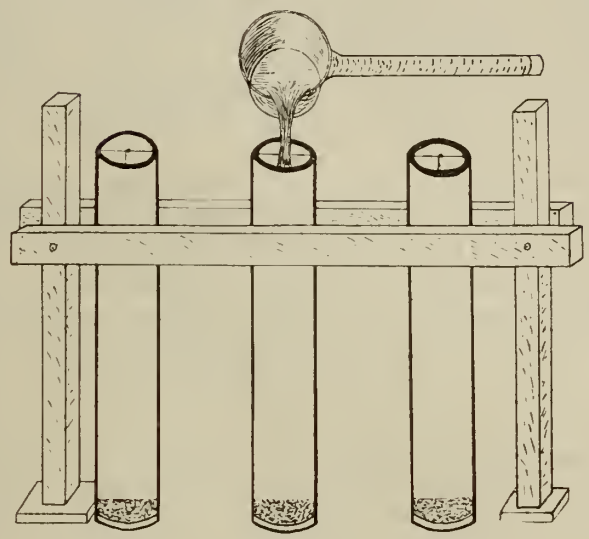

FIG. 2

results in a loss of packing. The header joints on the ends of the generator may also spring leaks. If this occurs take up the bolts, but if this fails to eliminate the trouble renew the gasket, being sure to renew both at the same time. When the leak is in the air the experienced operator has little trouble in locating it, but when it is into water, chemical tests are necessary. Various agents are used, the most common being red litmus paper. When dipped in water or brine containing ammonia this will turn blue. Nessler's solution causes the affected water to turn yellow and brown, while phenolphtalen causes a bright pink color when the slightest amount of ammonia is present.

Leaks in air can always be detected by the use of sulphur. Melt common sulphur and dip wicking into it, making a sort of candle, or the candles may be formed as shown in Fig. 2. The tubes should be made of sheet asbestos and the bottom plugged with fireclay, then pour the sulphur into the tube. Care must be taken not to set the sulphur on fire or to permit it to come in contact with the body as it cools instantly and produces painful burns. To test for leaks, light one of the sticks and hold it under the suspected joint. The sulphur fumes mingled with ammonia produce a dense grey-white cloud. Nessler's solution should be used instead of litmus paper if the leak is into brine. A precipitate will be formed almost white if no ammonia is present, and reddish brown if the brine contains considerable ammonia. Lead should not be used for gaskets on the high pressure side, for every time the line gets hot and expands, the lead squeezes together, and when the line contracts the joint is sure to leak, consequently such joints require constant tightening. Asbestos should be used, the gasket first being covered with cylinder oil, then brushed with graphite. Such a gasket will last indefinitely.

If there is reason to suspect the ammonia charge is contaminated draw off a sample and let it evaporate. If it all evaporates everything is satisfactory, but if a sediment and liquid remains the charge should be renewed or purified. This of course applies only to those systems in which a purifier is not installed. Another point to be considered is the scale and other matter which may accumulate on the outside of an atmospheric condenser. If this is not removed regularly the fuel and water consumption of the plant will be enormously increased. The practice of removing this by tapping with a hammer should be avoided as this may result in leaky joints. It is better to use a scraper, although the condenser may be kept reasonably clean by letting it be inactive for a short time, possibly a few weeks, which will cause a large part of the scale to loosen and fall off. In every case the engineer should keep a record of all temporary repairs which have been made during the running season so that these may be rectified when the plant is given the periodical general overhauling.

COKE FIRING

This is one of the best methods of firing soft coal by hand. It is known also as "bank firing," and consists in banking up a windrow of fresh coal across the front edge of the fire near the furnace doors, while leaving the coal on the rest of the fuel-bed at a white heat. The volatile parts of the fresh coal are distilled off by the heat, and in passing over the white-hot fuel bed they will usually be completely burned, if there is a sufficient amount of air present in the furnace to combine with them. After the volatile parts of the fresh coal have been distilled off, so that what remains is coked and thus transformed into practically pure carbon, the windrow is pushed back over the grates so as to cover them with a uniform layer. This is a very ancient method of firing.

The Buckeye Machine Co., Lima, Ohio, have issued a catalogue on the Buckeye Barrett oil engine. This publication describes the sturdy design of these engines which have been developed for operating on low grade fuel oil. In the design of the engine the makers have drawn largely on past experience and have adopted those principles which have proven themselves most efficient on continuous use. To these they have added the many special features required for the successful use of the fuel on which these engines are adapted to run.

Some Notes on Economizer Operation

Saving Effected — Importance of Removing Soot — Size of Economizer Necessary — Boiler Scale Elimination — Entrained Air and Its Effect in Increasing Corrosion—Scraping Mechanism

By E. CONN

THE economizer consists of a number of cast iron tubes and headers through which the feed-water passes on its way to the boiler and around which the waste gases of combustion pass on their way to the stack.

The purpose of the economizer is to heat the feed-water to a high temperature before it enters the boiler by means of the heat contained in the flue gases when they leave the boiler.

The rise in feed water temperature thus gained from heat, which would otherwise be wasted results in a greater evaporation in the boiler per pound of fuel burned and a corresponding fuel saving, or if desired, the same amount of fuel may be used with a proportional increase in the steaming capacity.

The average saving or increased capacity obtained by installing an economizer varies from 10 per cent. to 15 per cent., depending upon plant conditions, although in some cases greater savings have been made. Economizers show an unusually high return on the investment due to the large saving in proportion to the small cost of installation and they should be used in almost every boiler plant, especially as the conservation of fuel is a matter of national importance.

The standard boiler rating is 10 square feet of heating surface per horsepower and is based on the evaporation of 34.5 lb. of water per hour from and at 212° F. by the heat transmitted through that amount of heating surface or, in other words, the transmission of 33,480 B.t.u. per hour. Actual operating conditions, however, vary greatly from this, as the boiler may be operated at some point below this rating or perhaps at 400 per cent. of rating.

A percentage of the heat in the fuel always leaves the boiler in the flue gases. Table No. 1 shows the percentage of the heat of combustion present in the flue gases under various conditions.

HEAT OF FUEL PRESENT IN FLUE GASES

Flue Gas Temperature.	A	B	C
300° F.	.....	.....	12.4%
350° F.	.....	12.0%	14.9%
400° F.	.....	14.0%	17.4%
450° F.	12.2%	16.1%	20.0%
500° F.	13.8%	18.2%	22.6%
550° F.	15.4%	20.3%	25.2%
600° F.	17.0%	22.4%	27.8%
650° F.	18.5%	24.4%	30.4%
700° F.	20.1%	26.5%	.....
750° F.	21.7%	.....	.....
800° F.	23.2%	.....	.....

A. is based on using 18 pounds of air per pound of combustible in the fuel and represents average underfeed stoker operation with forced draft.

B. is based on using 24 pounds of air per pound of combustible in the fuel and represents average overfeed or natural draft stoker operation.

C. is based on using 30 pounds of air per pound of combustible in the fuel and represents average operation with hand-firing and natural draft.

Without the use of an economizer this heat would all be wasted, but by applying the "counter-current" principle and using the heat in the flue gases after they leave the boiler to heat the feed-water before it enters the boiler a large part of this heat may be saved.

By using an economizer the temperature of the feed-water may be raised from the water supply, hot well or exhaust steam feed water heater temperature to a temperature approaching that of the water in the boiler. The higher feed-water temperature thus obtained results in a proportionate saving in fuel as the transmission of less heat by the boiler surface combined with the heat recovered by the economizer will produce the same amount of steam as would be produced if an economizer were not used.

The actual saving that any economizer installation is making can be easily calculated from the following formula:

$$\text{Percentage saving} = \frac{100\,(T - t)}{(H + 32) - t}$$

where

T = temperature of feed-water after heating.

t = temperature of feed-water before heating.

H = total heat in steam above water at 32° F.

For example, assuming a feed-water temperature entering the economizer, of 180° F., a final temperature leaving the economizer at 310° F., and a boiler pressure of 150 lbs. per square inch above atmosphere—the actual saving would be:

$$\frac{100\,(316 - 180)}{1225.5 - 180} = 12.44 \text{ per cent. saving.}$$

Results under various conditions of feed-water temperature and boiler pressure may be approximated by estimating 1 per cent. saving of fuel for each 10° F. added to the temperature of feed-water.

Knowing the temperature of the gases leaving the boiler and desiring to find the saving that may be made by using an economizer to heat the feed-water by means of the heat which would otherwise be waste, take the temperature of the gases in the boiler uptake and assume a final gas temperature entering the stack of 300° F. in order to obtain the approximate drop in temperature through the economizer. Then as each 20° F. taken from the gases under average conditions will heat the feed-water 10° F., this will give the estimated saving.

The size of the economizer necessary to secure these results may be approximated by allowing 5 square feet of economizer heating surface per boiler horsepower developed under average conditions.

After the economizer is installed, great care must be taken to keep the external surface of the tubes, which are in contact with the hot gases, as clean as possible in order to prevent soot collecting on them, as this insulates them from the heat and materially reduces the rate of heat transmission, thus reducing the saving that might be obtained. In order to do this in the easiest and most convenient way, the manufacturers provide mechanically operated scrapers for this purpose. These scrapers consist of three parts, each part having a bevelled cutting edge at the top and bottom which encircles the tube. These cutting edges are both directed upwards and the parts are so supported that these edges are forced against the tube on the up stroke, thus dislodging the soot, which falls down between the bottom headers to the soot pit below the economizer and can then be removed at convenient intervals.

The mechanism for operating the scrapers and for reversing the direction in which they travel, is simple and effective. Power required for this purpose is small and is usually supplied by belt from a small motor, small steam engine for same convenient shafting.

Care should be taken to see that the scrapers do not stick, due to any unusual conditions, in which case the chains passing over the pulleys on the gearing frame simply slide over the surface of the pulley. As the scrapers are arranged in sets cleaning four sections of the economizer, the accumulation of soot due to this would render a large percentage of the heating surface inactive, as the ordinary economizer has from 6 to 12 such groups.

The feed-water should not be introduced into the tubes of the economizer at a temperature which combines the moisture in the flue gases, as this will combine with the sulphur in the gas to form sulphurous acid, which will attack the surfaces of the tubes causing external corrosion. Where the initial feed-water is below 90° F. and might cause this condition, the difficulty may be overcome by passing a small part of the heated feed-water from the discharge of

the economizer back to the feed-water line, where it enters the economizer and thus tempering the cold water.

Many waters used for boiler feeding purposes contain impurities which are precipitated when the water is heated in the economizer. Because of the slow motion of the water in the tubes these precipitates fall to the bottom and the economizer should be blown down at frequent intervals in order to remove them. In some cases the economizer should be washed out two or three times a year in order to remove all of the sludge which might accumulate. This is much easier and better than allowing these scale-forming substance to get in the boiler, where they would become baked on the tubes as hard scale, which is dangerous and also which is difficult to remove. The most common scale-forming substances are the bicarbonates of lime and magnesia. These are precipitated in the economizer when the water is heated to about 200° to 210° F. because the bicarbonate is reduced to the monocarbonate, part of the carbon dioxide being set free and the monocarbonate is insoluble. The sulphates of lime, which form the harder scale, are not thrown down in this matter, but become insoluble in part above 270° F. so that if this temperature is reached in the economizer they will be precipitated. Some of the salts of magnesia are decomposed at high temperatures and will also be precipitated in the economizer.

Air entrained in the boiler feed-water or poor circulation, due to irregular feeding, will cause pitting of the internal surfaces of the economizer and inspections should be made annually to determine the possible presence of this trouble in order to prevent this condition rendering the economizer unsafe for operation.

In conclusion it may be well to state that it is advisable to take up with the makers of economizers such as Green's Economizer, Ltd., Toronto, any questions relating to design and installation.

Power Plant Management; Mechanical Stokers—II

Various Stokers Described and Their Operating Characteristics Outlined—The Underfeed Stoker—The Galt Sprinkler Stoker—Summary of Features of Interest in the Design of the Various Types of Stokers

AS we have seen, the advantages of the mechanical stoker over hand-firing are as follows:

1. Even and continuous firing of the automatic stoker, as compared to the intermittent action of hand-firing.

2. Practically constant and uniform supply of air, which can be controlled to some etxent to meet actual operating conditions, as contrasted with the wide variations in air supply occurring in hand-firing with constant opening of fire doors and varying depth of fuel bed.

3. Continuous and automatic cleaning of fires, leading to development of better over-all efficiency.

4. Large savings in labor, due to the fact that one man can take care of 2,000 H.P. of stoker-fired boilers, as compared to 250 to 500 H.P. of hand-fired.

5. Saving in fuel cost through ability to burn lower grade of coal than can be handled to good advantage with hand-firing.

6. Practical insurance of smokeless operation.

Overfeed Stokers

Overfeed stokers are of two types—front-feed and side-feed. To the first type belong the Roney, Wilkinson and Acme stokers; to the second, belong the Detroit, Murphy and Model.

With the front-feed stoker, the grate, which is arranged in a series of steps, slopes at a considerable downward angle front to rear. Coal received from the hopper is caked under a short suspended arch, and is then fed forward and downward by the rocking action of the movable grates, aided by gravity. The clinker, working forward, is emitted at the bottom, being crushed by rolls in some types of installations. For convenience in handling, the dumping grate is frequently divided into several sections.

Front-feed stokers possess the important advantage of permitting easy passage of air through the fire, so that complete and efficient combustion is readily secured. On the other hand, their construction is such that if boilers must be continuously driven at high ratings, the grates may become over-heated. In order to avoid this danger of burning, with possible necessary renewal of grates, engineers usually prefer other types of stokers, if it appears probable that boilers must be operated above 200 per cent. rating for considerable periods of time. Front-feed stokers are either natural or forced draft.

The side-feed, or "V" stoker, receives coal from two magazines located on each side of what is to all intents and purposes a Dutch oven. At the bottom of the magazines are coking plates, against which the grates, which are inclined at a steep slope toward the centre of the furnace, rest at their upper ends. As the coal leaves the magazines, from which it is fed alternately and intermittently, it rests for a short time upon the coking plates. At this point the volatile gases are largely driven off, being mixed with air, which has been pre-heated by admission through the arch over the fire.

As combustion proceeds, the fuel travels slowly down the inclined grates toward the clinker grinder, receiving the requisite amount of air through the grates to complete the process of combustion by the time the lower portion of the grate is reached when the ash and clinker are automatically removed.

The speed at which the stoker boxes push the coal into the grates is, of course, subject to easy regulation. The grates being pivoted at their upper ends and actuated at their lower ends, agitate the fuel bed to a constantly increasing extent as combustion proceeds, thus permitting free admission of air and assuring complete combustion. In stokers of this type the clinker grinders can be adjusted to operate with reference to the amount of ash and clinker in the coal, irrespective of the action of other parts of the mechanism.

For boilers of moderate size, operated at 200 per cent. rating or less, the side-feed stoker makes a desirable and economical installation. It has the advantage of possessing a decidedly larger coking area than other types of stokers, and as the combustion area is likewise very large, it is possible, with careful manipulation, to secure complete and practically smokeless operation. Natural draft is the rule with this stoker.

The Down-Draft Furnace

While the down-draft furnace is not to be strictly classed as a stoker, since its use involves hand-firing, it nevertheless deserves consideration, since it performs certain of the functions of the mechanical stoker; that is to say, as compared to ordinary hand-firing, it permits the use of lower grades of fuel, assures practically complete combustion, and what is extremely important in many installations, smokeless combustion.

The down-draft furnace consists of two separate grates, one above the other, the upper grate being formed of a series of tubes opening at their ends into steel drums or manifolds, through which the water of the boiler circulates, whereas the lower grate is formed of ordinary

---

Editor's Note:—This is the seventh in a series of articles by Mr. June, on Power Plant Problems. Succeeding articles deal with principles of heat absorption, coal and ash-handling equipment, storage of coal, abuse of steam, etc. Later articles sum up the best current practice in the business management of the power plant. The series is of timely interest and should prove of value to our readers.

grate bars. The firing doors are near the top of the furnace, and the upper grate only is fired. This grate, it should be noted, slopes upward at a sufficiently steep angle to assure rapid circulation.

A division wall at the back of the furnace prevents the gases from going rearward, hence the draft is downward through the fuel bed, and the volatile matter, as it is evolved, passes directly between the grates into the combustion chamber. The lower grate is fired entirely by coked coal, falling through the tubes of the upper grate. As the flames from the lower grate arise they meet the down-coming gases, and the process of combustion is complete.

An objection sometimes raised to the down-draft furnace, is that it "cannot be forced above rating," but this is not strictly true, as it can be driven to nearly, if not fully, the same extent as a hand-fired furnace. When installed under conditions within its limitations it is more economical and satisfactory than hand-firing.

The Underfeed Stokers

Among the best known underfeed stokers, are the Taylor, Type "E," Jones, Riley, Westinghouse, and American.

The underfeed stoker is the stoker for large installations and excessively high ratings. Indeed, so completely has it pre-empted this field that it is unusual to go into a large central station or high-duty large boiler power plant of any sort, built within recent years, and find other types of stokers installed.

There are a number of reasons for this. First of all, the underfeed stoker is adapted to all grades and sizes of free-burning bituminous coal. Next, it is essentially a forced draft stoker, since it operates with restricted air openings and very deep fires. The forcing capacity is almost unlimited, instances being known where this stoker has been driven to over 400 per cent. rating.

Sufficient combustion chamber space is the principal consideration in making underfeed stoker installations, as with this stoker it is necessary to elevate the boiler a very considerable distance above the floor. Cooking arches or plates are dispensed with entirely. The principle of the underfeed stoker is that of a steam-driven ram, which forces the fresh coal into a large receiving retort, contained within the furnace, and from there up under the fuel bed.

The Jones stoker consists of nothing whatever except this retort, or a series of retorts, depending upon the size of the boiler. There are no grate bars and no ash-pit—just a blazing pile of coal, continually fed with new supplies pushed up from below. Air is admitted through hollow blast tiles at the upper edges of the retort. Ash and clinker form chiefly on the dead plate between the retorts, and are removed by hand at intervals of a few hours. Automatic control of air and fuel supply is secured, definite proportions of each being admitted as the steam pressure tends to rise or fall.

In the Type "E" stoker, the retort has a reciprocating sliding bottom, which carries the coal forward. It is delivered uniformly from front to rear, by auxiliary pushers, and as it rises in the retort, is distributed to the sides of the furnace by means of rocking-bars, so set as to slope both ways from the centre of the furnace toward the side walls. The progress of the burning coal and also of the ash and clinker is constantly toward the sides. By the up and down action of the rocking-bars the clinker is kept from forming in large pieces. Dump trays at the side permit cleaning by the act of throwing a single lever.

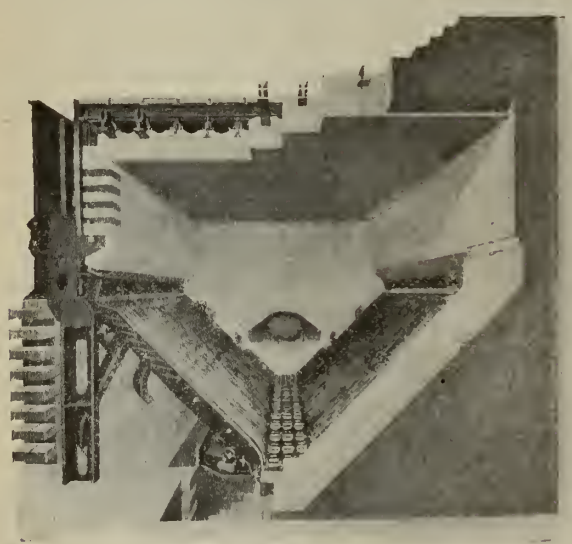
More elaborate than other underfeed stokers, the Taylor consists of a series of alternate retorts and tuyeres, sharply inclined toward the rear of the furnace. Each retort is filled with two rams—the upper for pushing the green coal inward and upward—the lower for forcing the fire toward the dump plates at the rear. The dump plates referred to are hung on the rear of the wind-box. They are controlled from the front of the furnace. This stoker may be operated efficiently and smokelessly at the heaviest known overloads, hence it is frequently found in the largest plants. Stoker and blower are operated by the same engine, and power required for this purpose is from 2.5 to 5 per cent. of steam generated, making it probably the highest steam user among the stokers.

The Riley is a multiple retort stoker, the distinctive feature of which is that the sides of the retort reciprocate relative to the bottom. This arrangement results in the fuel being moved at a uniform rate out of the retort and across the ash supporting plates until it is discharged through adjustable openings next to the bridge-wall.

Points to Remember Regarding Stoker Operation

Here are a few of the points to remember regarding stoker operation:

1. Draft must be under close control at all times.
2. Keep air vents open.
3. Look out for air leaks, particularly after making adjustment.
4. Make frequent flue gas analysis
5. Keep side walls clean of adhesions.
6. Do not stop stoker long with hopper full of coal.
7. In chain grates, make adjustment of gate and speed if fire tends to withdraw from gate or run over end.
8. Coking coal may require slice bar.
9. In washing out boiler, do not get water on arches or brickwork.
10. Do not pull dead plates entirely clear of ash.
11. Keep ash-pit cleared out.
12. Have all necessary maintenance work attended to promptly.



OVERFEED STOKER

UNDERFEED STOKER

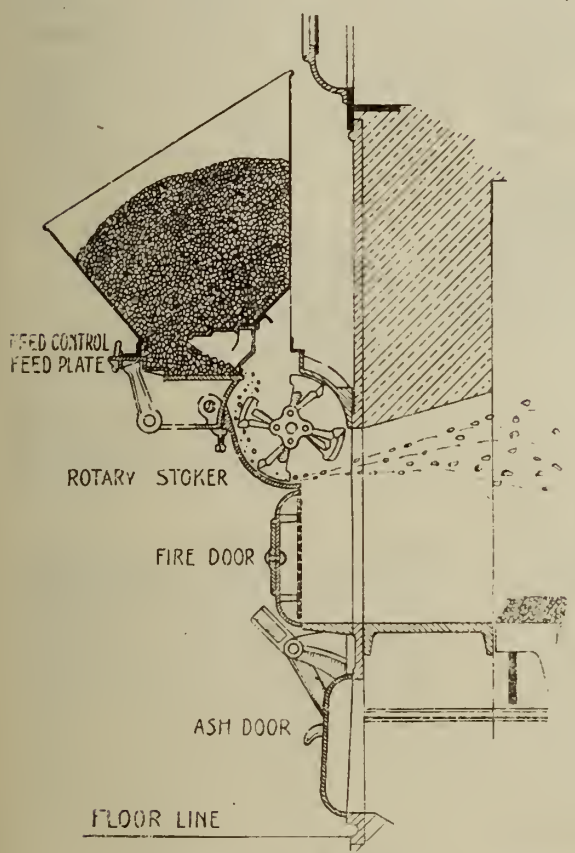
Summary

We have found that the chain grate is suitable for boilers of quite good size, up to 250 per cent. rating, and that its important characteristic is that grates must be designed for the fuel burned. We have shown the overfeed stoker is particularly suitable for medium sized

installations, up to 200 per cent. rating. The down-draft furnace, particularly for small boilers operated at non-excessive ratings, offers a comparatively inexpensive substitute for certain functions of the mechanical stoker. And finally, we have placed the underfeed stoker as the apparatus for large boilers, operated at extremely high ratings.

Sprinkler Stokers

The sprinkler stoker is one of the best known to Canadian power users—a circumstance attributable perhaps to the



GALT SPRINKLER STOKER

fact that the Canadian manufacturer of this type of stoker, the Galt Foundry Company, has developed it to a point of greater efficiency and capacity than it has attained elsewhere.

The principle of operation of the lustration. The apparatus is bolted to a frame casting in front of the setting. Coal of nut size or smaller is fed into a hopper, from which it gravitates onto a feed plate. From the latter the fuel is fed to a rapidly revolving crusher and spreader.

This apparatus consists of heavy pieces of cast steel, so designed as to throw the coal in various directions. Several of these spreaders are so arranged on the shaft that adjacent sections throw the coal, after it has been ground into small particles, over different sections, thus covering the entire surface of the bed.

Advantages of the arrangement are obvious. Powdered and fine coal is burned in suspension, and larger pieces, falling on the bed, burn with great rapidity. A thin, level, brilliant fire is maintained, and complete, smokeless combustion secured.

The stoker is, of course, not self-cleaning, that is, ashes must be removed by hand, or by suitable shaking grates. This does not alter the fact, however, that the stoker is greatly superior to hand-firing—both as regards results, and conservation of labor. It possesses the important advantage of low cost of maintenance, since there are no parts to burn out. The sprinkler stoker is particularly suited for small and medium-sized boilers, operated at normal high ratings.

FRICTION FABRICS

By H. A. L.

The material wherewith to line clutch and brake surfaces has always been a problem. In railway work the cast iron shoes wear out rapidly, and it is considered more economic to have the metallic wastage upon the easily-renewed and cheaply-produced brake shoe than on the xepensive tire. At the same time the metallic wastage irrecoverable as scrap must be very large. In the motor car the cone clutch largely used has most often a leather lining, while the brakes are steel bands over drums, which serve to give the braking effect when controlled from the dishboard.

Recent solutions of the problem have led to the marketing of textile fabrics of special type for which large claims are made. One of these materials seems to have disappeared, but the other is rather prominent.

Both claimed an asbestos foundation, and are supplied in a form resembling belting or braid of very coarse texture. As in the case of engine packing, the experienced engineer is always somewhat curious and sceptical, and while no doubt is cast upon the efficacy of the materials the result of a close examination is interesting. At first sight the resemblance to what is known as wire woven, high-pressure packing is considerable, the chief feature of the construction seems to be the combination of a single brass wire of fine gauge as the core of a rather coarse textile thread. High pressure packing is similar in construction, the asbestos fibre being rolled or carded on to a wire core. This reinforced or composite thread is then woven into the familiar forms.

In the case of the material discussed, the claim as to the inclusion of asbestos seems hardly warranted, for the thread seems to consist of a large proportion of fibre other than asbestos. It was claimed at one time that old sail canvas made the best canvas engine packing, universally known as Tuck's, the stretch having been taken out of the fabric by prior use. At the same time such material is initially cheaper, and the economic factor would probably be a greater incentive than the reason alleged. However this may be, in the friction lining similar material seems indicated, the fibre looks more like old rope, either hemp or manila. It has occurred to the writer that the inclusion of asbestos is to minimize overheating in the absorption of power by friction. The rope used in the Prony brake does occasionally smoke, but not usually, unless its proportions are inefficient and it is grease saturated, when its liability to overheat is similar to that of oily waste. The presentation of a wire mesh surface by wear in conjunction with a textile material of frictional qualities finds a precedent in the non-slip stair tread, where lead and steel or cast iron form a composite surface, the harder material, whether as straight lines or woven wire diminishing wear while allowing the softer metal to exercise its non-slipping qualities. Lead in this particular is the safest material known, even when greasy, or otherwise rendered in a condition where other metals would provoke accident. The tendency to slip on greasy M. S. chequer plates is very pronounced. Asbestos being immune from any tendency to fire, and since it can be procured wire-woven it is a little surprising that the ordinary commercial material used everywhere for engine packing should be unknown as a brake lining. Perhaps it is the initial cost of such high grade packing, but the results of any tests would prove interesting. The material marketed under a trade name is certainly cheaper to produce so far as a detailed examination would show, but if engine packing of the type indicated serves the same purpose this should exert a salutary check upon any undue price. It certainly seems open to the engine packing maker to heavily adulterate his product with alien fibre of cheaper character and make this up in suitable dimensions. To add to its resistivity some drying oil or resinous substance may also help its friction qualities.

In the death of Julius E. Waterous, which took place at his home, Bonnythorpe, Brantford, on January 11, the city lost one of its industrial leaders. He was one of the founders of what is now the Waterous Engine Works, one of that city's largest industrial plants, with which he was connected as mechanical manager and vice-president until he organized the Waterous Works, which he successfully conducted until he retired from active business in 1910. He was seventy-five years of age at his death. He is survived by his wife, formerly Miss Annie Van Someren, and two sons, Reginald and Bertram, who have just returned from overseas, where they were connected with the Canadian Artillery. Among the works with which Mr. Waterous was connected were the waterworks plants at Windsor, Orangeville and Lindsay, constructed under his supervision, following the installation of waterworks in his home city, the first in Canada.

Armature Testing and Trouble Localization

The Following Article Describes Various Methods in Use For Locating Faults Which Are Likely to be Encountered in A.C. Armature Circuits and Gives Means For Their Quick Localization

By TERRELL CROFT,
(Copyright by the Author, all rights reserved)

DIRECT-CURRENT armatures can be tested for the common troubles with the arrangement of Figs. 1 and 2. Terminals *b* and *c* are clamped to the commutator at opposite sides and connected with a source of steady current through an adjustable resistance and, preferably, but not necessarily, an ammeter. The terminals of a low-reading voltmeter (a galvanometer can

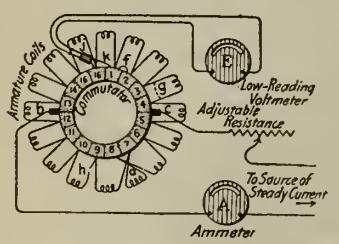


FIG. 1—METHOD OF TESTING AN ARMATURE

often be used) are connected to two bare metal points, or "exploring terminals," which are separated by an insulating block *j*, Fig. 1. Exploring terminals may also be arranged as shown in Figs. 2 (*II*) and 3. In use, the current is adjusted to produce a convenient deflection of the voltmeter when each of the points rests on an adjacent bar. The points are moved around the commutator and bridged across the insulation between every two bars. If the voltmeter deflection is the same for every pair of bars it indicates that there is no short circuit in the armature.

In testing armatures where only alternating current or low-voltage cells are available, a telephone receiver (Figs. 4, 5 and 6) may be used instead of an electrical-measuring instrument for a detector. The variations in or appearance or disappearance of the sound in the receiver, as the test is being conducted, enables the operator to localize the trouble. The alternating current (Fig. 4) will cause a hum in the telephone receiver and the pulsating current produced by the vibrator (Figs. 5 and 6) effects the same result. The vibrator may be an ordinary vibrating bell or buzzer conected in series in the circuit as shown in the illustrations.

High-voltage alternating current for testing armatures is sometimes used (Fig. 7) for high-resistance grounds which may not be detectable where a low e.m.f. is used for testing. Such high-resistance grounds may not in normal operation make their presence known until there is also a ground on the supply system feeding the motor. In using this apparatus the procedure is merely to connect one terminal, *A*, of the high-voltage source to the commutator, and the other terminal, *B*, to the shaft. When the high voltage, *EH*, is impressed on the armature, this will, usually, break down the insulation at the weak point and render the location of the ground apparent by the smoke which will emanate from the point of breakdown. Fuses, er circuit breaker C_1, C_2, should be inserted in the supply circuit to prevent the disastrous effects of a short-circuit.

An alternating-current inducing coil is sometimes used for localizing armature troubles. Such a coil is illustrated in Fig. 8, while the methods of its application are illustrated in Fig. 9. The inducer is merely an alternating-current magnet having a U-shaped core composed of sheet steel laminations. The laminations should be interleaved and hinged at the point *H* so that the core may be opened or closed to most effectively accommodate armatures of different diameters. In use the core should be opened to such a width that its two poles, P_1 and P_2, will have a separation corresponding to the throw of one armature coil. As shown in Fig. 9 the poles should not touch the armature iron when a test is being made, but an air gap of approximately ¼ inch should be allowed.

The principle of operation of the inducer is this: The alternating flux developed by the current in the inducer winding sets up an e.m.f. in the armature coils and if a coil is short-circuited it will cause a current to circulate in that coil. Thus, in making a test the excited inducer is held over the armature, which is rotated. Now, if the armature is slowly rotated, while a small piece of metal is held lightly on the commutator so that it will bridge the segments between each of the bars there will be, as the armature is rotated, an arc produced each time one of the segments is bridged, provided the segments connect to a normal coil. But, if a coil is open, short-circuited or reversed, there will be no sparking. To determine whether the difficulty is due to an open or a short-circuit, the small iron test strip is bridged across the armature slots. Where the coil is short-circuited the induced current which will flow in it will create a flux around the sides of the coil which can be detected with an iron test strip which is moved over the armature coil slots. Furthermore, a short-circuited coil will be quickly heated by the local current flowing in it.

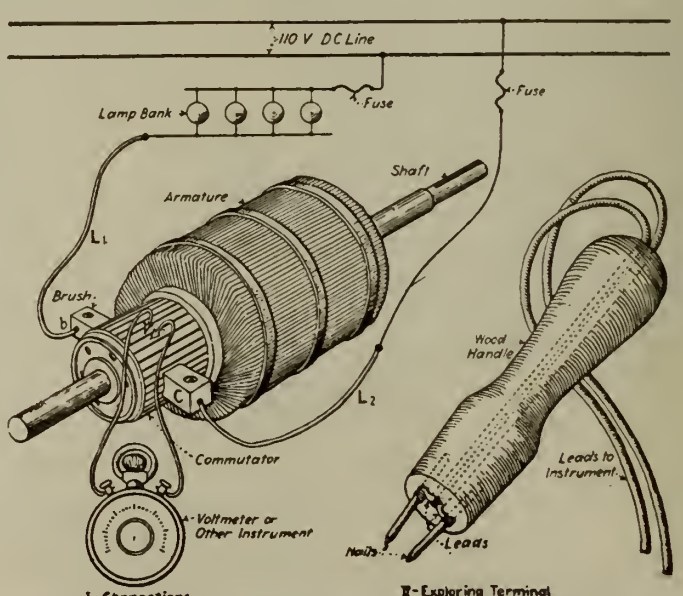

FIG. 2—CIRCUIT AND EQUIPMENT FOR TESTING DIRECT CURRENT ARMATURES FOR TROUBLE WITH DIRECT CURRENT.

The telephone receiver detector used with the inducer, Fig. 9, affords a more

accurate but somewhat slower method than that described in the preceding paragraph. To locate a short-circuit, Fig. 9, *I*, an exploring terminal connected to the receiver is held on the commutator while the armature is rotated. When the exploring points are bridging a normal coil there will be a hum in the receiver due to the induced alternating current flowing through it. When the points bridge a short-circuited coil there will be little or no hum in the receiver, depending upon the number of short-circuited turns. When the exploring needle points bridge on open coil, an alternating current of considerable intensity will flow through the receiver and a loud click will be heard. Where a coil is reversed several of the coils adjacent to it will test "silent." To definitely locate the incorrectly connected coil it will be necesary to raise some of the coils and trace them out by inspection. To locate a ground, the connections are made as shown in Fig. 9 *II*, and the armature is slowly rotated. When, as the armature is rotated, contactor C is on the segment connecting to the grounded coil, no sound will be heard in the receiver but at other locations there will be a sound, the sound diminishing in intensity as the segment connecting to the grounded coil is approached. For locating partial grounds this method may be ineffective, in which case that involving a high alternating voltage whereby an insulation breakdown may be produced, should be employed.

A rack for testing small armatures using the methods of Figs. 1, 4 and 5 is detailed in Fig. 10. Ordinarily a man and a helper are necessary in testing out an armature, but with the appliance shown one operator can locate the faults

A convenient arrangement of a test lamp and exploring terminal is shown in Fig. 11. The flexible cord and the indicating lamp, which also serves as a resistor for limiting the current, and the exploring terminal, can be cut in series with the supply circuit by means of a fuse connector as detailed in Fig. 12. With this arrangement the testing set can be quickly cut in service at any point where there is a cut-out. Where it is used it may be necessary to close the line with a temporary switch or otherwise on the load side of the cut-out. An Edison plug or a ferrule contact fuse can be used instead of the knife blade contact fuse of Fig. 12 by adopting obvious modifications.

A poor connection between a bar and coil leads will cause a considerable deflection of the voltmeter (Fig. 1) when one of the points rests on the bar in trouble and the other rests on either of the adjacent bars.

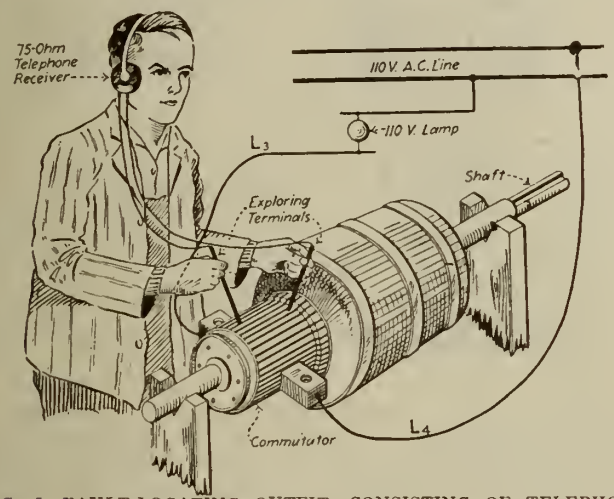

FIG. 5—FAULT-LOCATING OUTFIT, CONSISTING OF TELEPHONE RECEIVER, VIBRATOR AND DRY CELLS.

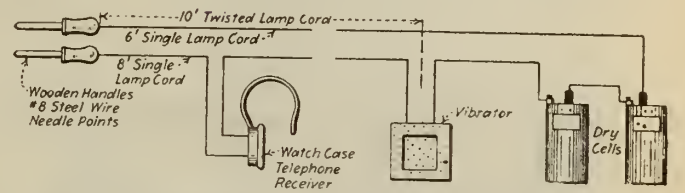

FIG. 6—CIRCUITS FOR LOCATING FAULTS IN AN ARMATURE WITH A LOW VOLTAGE SOURCE AND A VIBRATOR.

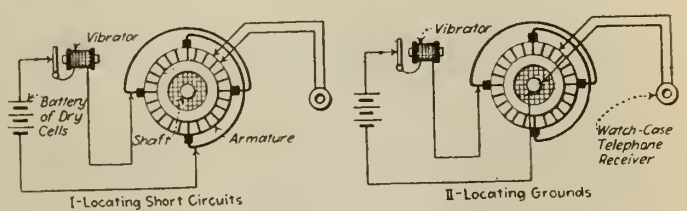

FIG. 7—METHOD OF OBTAINING AND APPLYING HIGH POTENTIAL FOR ARMATURE FAULT LOCATION.

An open-circuited coil, as *h*, Fig. 1, will prevent the flow of current through its half of the armature. There will be no deflection on that half of the armature until an "open' is bridged, when the voltage of the testing circuit will be indicated.

Tests for Open Armature Circuits.—Another method, (Fig. 13), is to apply to the commutator at two opposite points, a low voltage, say from a battery or from a dynamo with a suitable resistance (incandescent lamps for example) in series. Place an ammeter in circuit and clean the surface of the commutator so that it is bright and smooth. The terminal ends leading the current into and out of the commutator should be small so that each rests only on a single segment, Fig. 13. Note the ammeter reading and rotate the armature slowly. At the point where the open circuit exists the ammeter needle will go to zero if the leads to the commutator bar have become entirely open-circuited. This is because the segment is attached to the winding through the commutator leads.

If the armature does not show the above systems try connecting a low-reading voltmeter or a galvanometer to two adjacent segments while the current is passing through the armature as described from some external low-voltage source, Fig. 14. Note the deflection. Pass from segment to segment in this manner, recording the drop between the successive pair of bars. This drop, if the current is maintained constant from the external source, should be the same between each pair of adjacent segments. If any pair shows a higher drop than the others near it, a higher-resistance connection exists there, perhaps causing sparking of the commutator insulation to a less degree, probably, than with an actual open circuit, but enough, perhaps, to cause trouble.

The test for armature short-circuits, described in the preceding paragraph, is called a "bar to bar" test. It is most valuable in locating faults in armatures. It is the method to use if a short-circuit from one segment to another is suspected. When the section in which the short-circuit, or partial short-circuit, exists comes under the contacts, a low or perhaps no deflection is shown on the galvanometer or voltmeter, thus locating the defective place. Such short-circuits, if they occur when running, owing to defective insulation, burn out the coil short-circuited. When the coil passes through the active field in front of the pole-piece, an immense current is induced in it, causing a destruction of the insulation. When this occurs the coil should be open-circuited if the burning has not already short-circuited it. If practical it should be bridged over.

If two bars or a coil is short-circuited as at *f* and *g* (Fig. 1), respectively, there will be little or no voltmeter deflection when the two bars connecting to the "short-circuit" are bridged by the point.

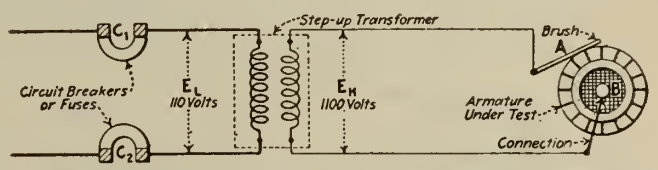

FIG. 4—ILLUSTRATING A METHOD OF LOCATING FAULTS IN AN ARMATURE WITH ALTERNATING CURRENT.

A grounded armature coil can be detected in practically the same manner as indicated in Fig. 15 for a field coil. Fig. 16 shows the connections. Impress full voltage on the terminals *A* and *B* clamped to the commutator. Ground one side

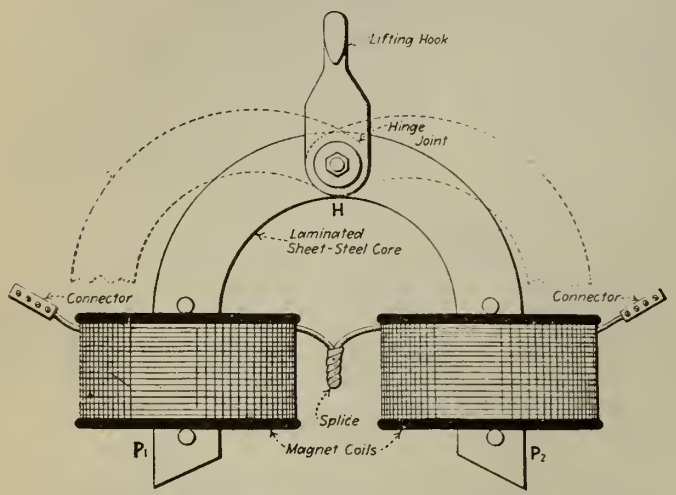

FIG. 8—"INDUCER" USED FOR LOCATING FAULTS IN A DIRECT CURRENT ARMATURE WINDING—INDUCES AN ALTERNATING E.M.F. IN THE ARMATURE WINDING.

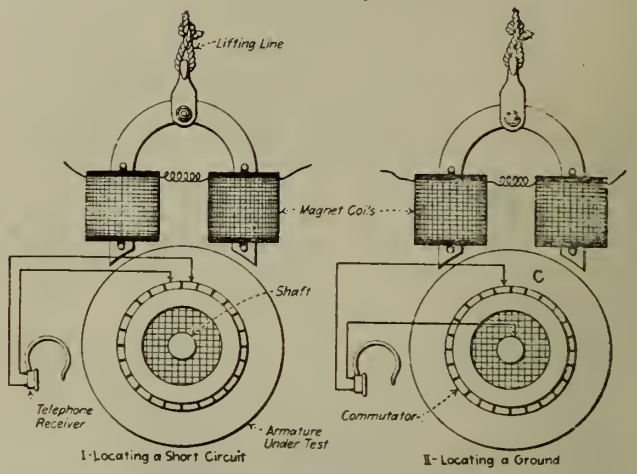

FIG. 9—ARRANGEMENTS FOR LOCATING SHORT CIRCUITS AND GROUNDS WITH ALTERNATING CURRENT INDUCER.

of the voltmeter on the shaft or spider, as at *C*, and touch a contactor *C* connected to the other side of the voltmeter to all the bars in succession. The minimum deflection will obtain when the bars connecting to the grounded coil are touched. A battery of dry cells, *E*, (Fig. 16), having in series a resistor, *R*, may be used as a

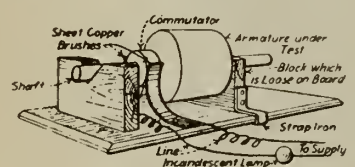

FIG. 10—RIG FOR TESTING SMALL ARMATURES (ELECTRICAL REVIEW).

source of energy. A bank of lamps connected in parallel will serve as a resistor. Instead of using a voltmeter as in Fig. 14, a galvanoscope, *F*, (Fig. 16) may be used. Such a galvanoscope may be improvised by winding a coil of wire around a pocket compass, but where this device is employed the galvanoscope must be used far enough away from the machine under test so that the compass needle

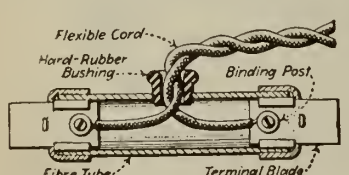

FIG. 12—SECTIONAL ELEVATION OF FUSE CONNECTOR.

will not be affected by the magnetization of the machine under text.

Crossed coil leads as at *g* (Fig. 1) are indicated by a twice normal deflection when the points bridge the bars to which the crossed coils should rightly connect. The crossing of the coil leads connects two coils in series, hence causes twice normal drop. Bridging the bars to which coil *h* connects will produce a normal deflection, but it will be reversed in direction.

Reversed armature coil.—Instead of the armature winding progressing uniformly around from bar to bar of the commutator, there may at some point be a coil connected in backward. Such a reversed coil often causes bad sparking. One way to locate such a trouble is to pass a current through the armature, at opposite points on the commutator. Then with a compass explore around the armature the direction of magnetism from slot to slot. If a coil is reversed when the compass comes before it, the needle will reverse, giving a very definite indication of the improperly connected coil.

Heating of armature.—Heating of the armature may develop from any of the following causes: (a) Too great a load; (b) a partial short-circuit of two coils heating the two particular coils affected; (c) short-circuits or grounds on armature or commutator.

Hot Armature Coils. — Sometimes, when a new machine is started, local heating occurs in the armature, following the exact shape of the armature coil. This may be because, in receiving its final turning off the commutator bars were bridged with copper from one segment to another by the action of the turning tool. An examination of the commutator surface will reveal this bridging. When it is removed, satisfactory operation will ensue if the trouble has not gone too far and seriously injured the insulation of the soil.

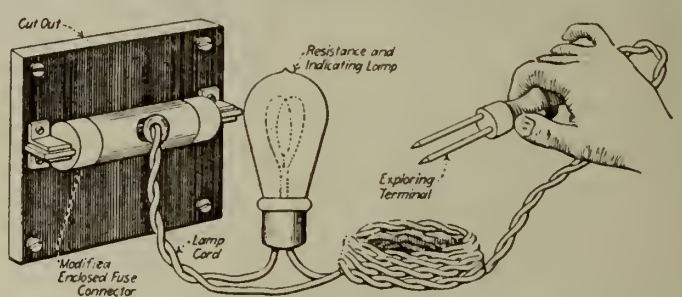

FIG. 11—SHOWING APPLICATION OF THE MODIFIED FUSE CONNECTOR FOR CONNECTING TEST LAMP IN SERIES IN THE TESTING CURRENT.

"Flying grounds," "flying short-circuits," and "flying open-circuits" sometimes occur in armature windings. These are intermittent troubles which may assert themselves when the machine is hot, after running under load, and its component parts expanded. Then, when it cools, the trouble may automatically correct itself. Sometimes the reverse con-

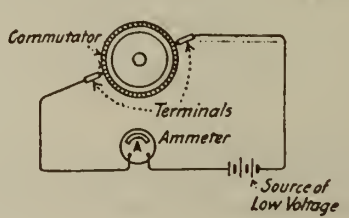

FIG. 13—TESTING FOR ARMATURE OPEN CIRCUIT WITH AN AMMETER.

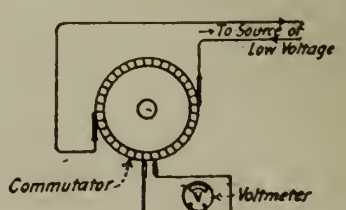

FIG. 14—TESTING FOR ARMATURE OPEN CIRCUIT WITH A VOLTMETER.

dition occurs, that is, the fault will be present when the machine is cold, but will be temporarily corrected when it is hot. Furthermore, centrifugal force, due

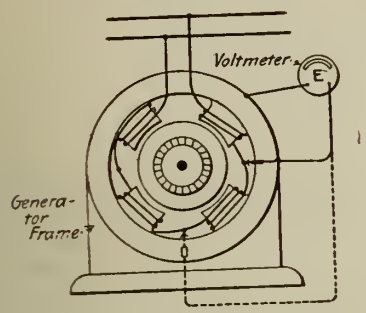

FIG. 15—LOCATING A GROUNDED FIELD COIL.

to the rotation of the armature, may be a factor in the situation, in which case the defect may be present when the armature is rotated at normal speed, but not present when the armature is stationary. Obviously such troubles are very difficult to locate. About the only

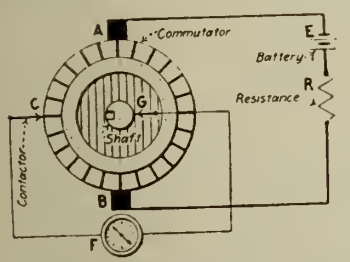

FIG. 16—ARRANGEMENT OF CONNECTIONS FOR LOCATING GROUND IN AN ARMATURE.

way to localize them is to run the machine until the defect has "burnt itself out" or otherwise rendered its presence sufficiently evident that it can be located by the usual testing methods described above.

QUICK-MAKE STARTING SWITCH

One of the new equipments brought out by the Westinghouse Electric and Manufacturing Company during the past year is an interesting starting switch. The switch is designed for use where squirrel-cage motors are started with a full line voltage. The switch is known as the Quick-Make (and quick-break) Starting Switch (Type 816). Its characteristics are 10 to 100 amperes, 25 h.p. maximum, three-phase, 220, 440, and 550 volts.

This switch is extremely flexible in its applications; in addition to being a motor starting switch it can also be used to control feeder circuits; it may be supplied in any of the following combinations, each having the "quick-make and quick-break" feature, for either hand or shipper-rod operations:

(a) Non-automatic switch.
(b) Switch with low-voltage protection.
(c) Switch with inverse time element overload protection.
(d) Full automatic switch with low-voltage and inverse time element overload protection.

It is especially suitable for shipper-rod operation on account of the positive action of the contacts. It is impossible for the operator to retard the motion of the contacts after they have started to close—there can be no "teasing" of the contacts. Workmen who are accustomed to starting machines from line shafting by means of shifting belts have no confusing details to learn. They may start the motor-driven machine with the same starting motion they use in shifting belts.

Contacts are opened and closed in oil, thus effectually suppressing arcing. The contact is made or broken so quickly that the eye cannot follow the motion. A rolling action confines the arc to the tips of the contacts and prevents pitting or roughening of the seating parts where final contact is made. A strong spring holds the contacts firmly in the closed position. These features result in greatly prolonged life for the contacts.

Construction.—Drawn-steel construction is used, giving maximum strength with light weight, and assuring uniformity and interchangeability when new parts are needed for replacement or repairs. The oil tank is supported by snap ring-latches. Removal of the tank clearly exposes the contacts and makes them easily accessible. When necessary to replace contacts each may be removed by taking out a single screw.

Contacts and contact supports are of the same construction used for Westinghouse type A auto-starters and magnetic contractors. This minimizes the number of spare parts that should be carried.

SWITCH COMPLETE

These starting switches are dust-proof.

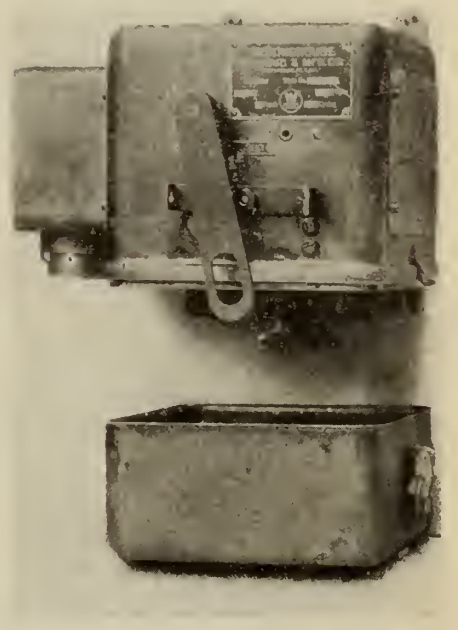
Openings are provided for conduit wiring into the top of case; terminals for connecting motor and line wires are accessible when cover at top of starter is removed.

Micarta insulation is used throughout.

Overload and low-voltage attachments may be added with no change in switch mechanism, as the toggle trip is common to all combinations of this switch.

Low-voltage protection not only opens the contacts on failure of power, but makes it impossible to close them again until return of voltage. Since the low-voltage coil is connected in the line circuit continuously, means have been provided to close the armature of the low-voltage circuit when the switch is in the "off" position, thereby giving protection to the coil and preventing burnouts. A safety stop may be provided by connecting one or more push buttons in series with the low-voltage coil.

Overload Relay.—The overload relay



SWITCH WITH CASE REMOVED

is the same as that used on Westinghouse type A auto starters. It has the inverse time element feature and is equipped with a regulating device, adjustment of which controls the degree and duration of the overload possible on a motor or feeder circuit. This adjustment can be made without opening the switch cover.

Hand Reset. — This is an additional safety feature which makes it necessary to set the mechanism before the switch contacts can be closed. Whether the contacts have been opened through the operation of the low-voltage coil, the overload relay, or by moving the switch handle to the "off" position, it is impossible to close them again until the switch handle has been moved to the "reset" position. Thus protection is afforded workmen and valuable machinery which might be injured by accidental starting of the motor.

The Puget Sound Traction, Light and Power Company's Western Avenue plant in Seattle, a central heating station containing 10 boilers aggregating 4,100 horsepower, has replaced oil fuel with pulverized coal. The pulverizing plant is situated directly across the Avenue, the product being conveyed underground and delivered to feeding bins above the boilers. Coal prepared at this plant is also distributed by truck to a number of large buildings having their own heating plants. The station is believed to be the largest of its kind that is using powdered coal.

The Control of Large Amounts of Power II

The Author, in a Paper Read Before the Institute of Electrical Engineers, England, Gave Some Interesting Remarks Regarding Control of Large Amounts of Power and the Use of Reactances

By E. B. WEDMERE

A STUDY of the data now given will bring out the disadvantages associated with the low power factor prevalent in distribution schemes in this country, and it will appear that the requirements for maintaining supply, as well as the conditions for diminishing losses, will be improved if a higher average power factor, such as 90 per cent., is obtained. In these respects present-day American practice has the advantage.

The Interconnection of Stations

Where relatively small and remote sources of power are coupled to a large system they improve the supply in their immediate neighborhood. It will generally be found that the inherent reactance in the feeders and transformers is sufficient to prevent excessive increase of short-circuit currents in the neighborhood.

Where the source is near a large station, it may be treated like a generator tied direct to an extension of the busbars, but will probably have more reactance than a single machine of equal output.

Where large stations are tied together this connection is similar to that between adjacent sections of busbars in an individual station, but differs in that a relatively smaller energy transfer is required, so that higher reactance may be employed. The energy transfer is made only for purposes of economy, and the individual station is already a self-contained economical unit. The short-circuit currents from individual sections in either station will not be materially affected if there are already three or four sections or more.

If the stations are not tied directly, but only through the distribution system, intermediate points will be subject to the short-circuit outputs of both stations.

Limitations Affecting Parallel Running:—The question now arises how will the employment of reactances between sections affect parallel running. This becomes particularly important in the case of stations remote from one another tied together for economy. Such ties may not be of large cross-section and may, therefore, introduce considerable resistance.

The theoretical treatment of this and similar cases has not been entirely satisfactory, but we may recognize that there are lower and upper limits to the reactance between which we can get satisfactory operation. It has been found that it is not generally practicable to obtain stable running conditions where the ohmic value of the total reactance in circuit between the machines is less than about twice the resistance. This necessitates the employment of external reactance in series with long underground tie cables of small cross-section. Where, however, there are step-up and step-down transformers in the circuit there will be ample reactance.

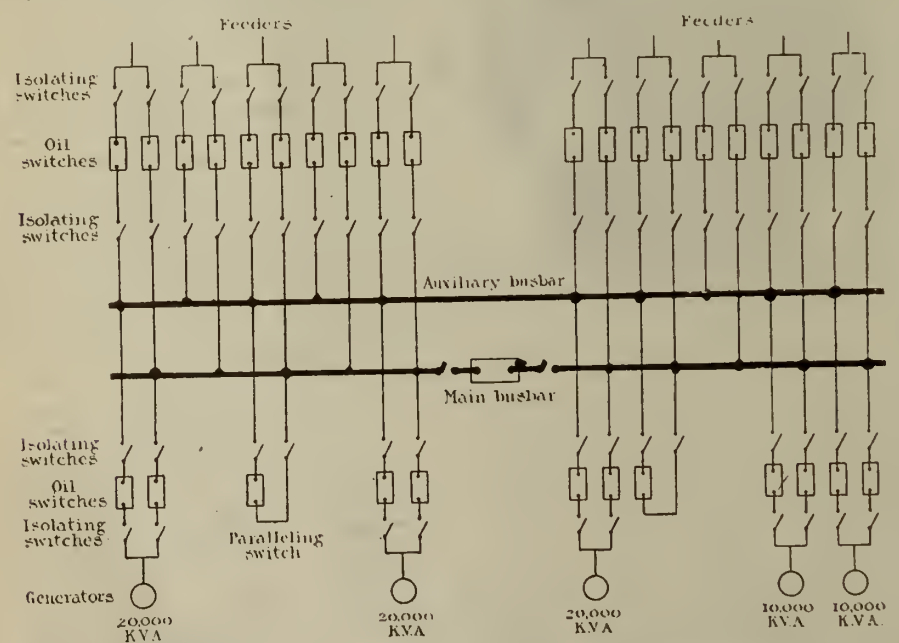


FIG. 7—ARRANGEMENT OF SWITCH GEAR, SHOWING DUPLICATE BUSBARS.

There must be an upper limit also, and this also is not easy to determine. It is evident that if two systems are running steadily at about the same frequency and voltage, a very small transfer of energy and magnetizing current passing through a high reactance will bring the two systems into synchronism. If now one system is seriously disturbed it will get out of phase with the other, but the small currents transferred will be insufficient to disturb the sound system and

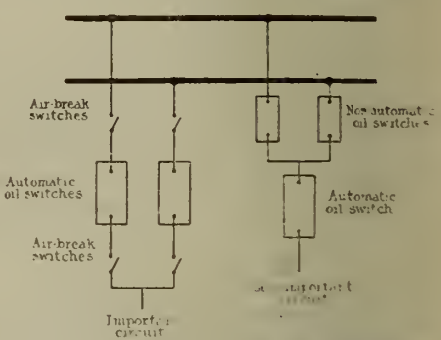

FIG. 8—DUPLICATION OF OIL SWITCHES.

will eventually bring the system into synchronism after conditions have become normal and steady. Here we have parallel running without trouble but without utility.

If now we reduce the reactance in the tie we get heavier synchronizing currents and some disturbance of the sound system, but the two systems take time to settle down after a fault is cleared on one of them, and during this time there is much phase-swinging. This oscillation tends to throw out synchronous machinery and is more serious than mere loss of voltage. The limiting values of reactance are somewhat indefinite, but experience indicates that they are well above the value contemplated in this paper. It is known that with the star design quite satisfactory results can be got with busbar reactances of 40 per cent. and more based on the section output, and upwards of 100 per cent. has been employed in a tie line between two stations.

Influence of Live Load on the Short-Circuit Current

In estimating the effect of reactance on the short-circuit currents no account has been taken hitherto of the influence of running machinery able to feed current back into a fault. This factor is generally a relatively small one. It complicates the issue but must not be lost sight of. In determining the short-circuit current that may flow at any point it is necessary to add the current, due to such machinery, which will flow through the impedance of any feeders, transformers, etc., located between the machines and the point in question.

The short-circuit current, for example, near a large substation with rotary converters may be considerably increased by

the current the converters can pump back.

Limited Effect of Fault Resistance

One must not expect to find any protection from internal resistance of faults, except when the fault is to earth through a poor earth connection or includes a long open arc.

Where porcelain insulators are mounted in brick or stone the supporting wall reinforces the insulation, and, even if a cracked insulator discharges, the current at 6,000 volts will be quickly reduced from perhaps 5 amperes to a negligible figure as the wall dries by the heat generated.

The development of a fault is sometimes stopped at an intermediate stage by quick-acting switchgear set to operate at a few amperes, but this is not a means which can be relied on for effectively limiting the stresses at a given point in the system.

Limiting Stresses by Preventing Faults Between Phases:—As faults to earth can be positively limited by the employment of resistance in the earth connection, it is only faults between phases that present a serious problem. The likelihood of such faults occurring can be greatly minimized by appropriate design.

When conductors are air-insulated they may be separated by substantial insulating barriers and kept clear of earthed metalwork. The barriers should be sufficiently large and substantial to confine the disturbance arising on failure of the apparatus they separate.

Conductors surrounded with insulating material may be further separated by earthed metal barriers so arranged that a fault to earth is confined to the phase on which is occurs.

A good example is found in a machine in which the conductors throughout their length, including the end turns, are covered with insulating material and separated by earthed metal parts with which they are in intimate contact. A breakdown on such a machine must arise as a fault to earth, and is localized by the formation of a good enclosed conducting path to earth. The risk of open arcing is minimized, and consequently the risk of the fault spreading to other phases of consuming the whole machine.

Limiting Disturbances by the Use of Protective Relays and the Like

The advantages obtained by the use of selective protective apparatus on large distributing systems are now generally recognized. They play an important part in economical distribution and an essential part not only in localizing disturbances but in limiting their duration. This latter function is useful in preventing the development of disturbances due to unstable conditions, as, for example, in parallel running, but is especially important on large plants where the factor of safety against overheating on short-circuits is likely to be small.

The use of such apparatus throws a severe duty on the switchgear, as switches have to clear faults whilst the currents are in the neighborhood of maximum value (see Fig. 1), and the onus of clearing each particular fault is thrown on the individual switch or switches nearest to it.

For these reasons it is necessary to employ with the selective protective apparatus a system of stand-by protective apparatus which comes into use in case of failure of switchgear or selective apparatus. This takes the form of a system of fixed time-limit relays with graded settings which will come into operation only after failure in the first line of defence. A plant so protected will be as well off even on failure of the selective apparatus or distribution switchgear as plants have been in the past which were protected solely by the apparatus now used as a stand-by.

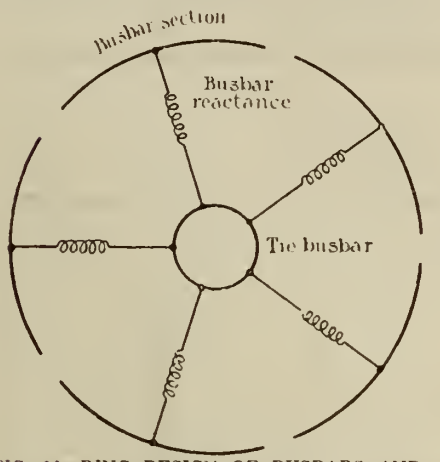

FIG. 10—RING DESIGN OF BUSBARS AND REACTANCES.

It is clear, therefore, that the provision of an adequate stand-by system justifies working with a lower factor of safety on the smaller circuits, especially if the conditions are favorable and the plant well designed in the first place to minimize the occurrence of severe faults. Existing switchgear may be retained on extension of plant, by relying on the stand-by protection to save the plant, if the margin is not too small.

For example, switchgear rated at 20,000 k.v.a. might be employed to clear faults of 30,000 to 40,000 k.v.a. with stand-by protection, as, if the conditions are favorable to the switch, even the larger faults may be cleared satisfactorily and the severest disturbances should be few and far between.

Rating of Reactances

In discussing the use and characteristics of reactances it is most convenient to rate them in terms of the percentage reactive voltage drop they will give on the full-load rating of the part of the plant with which they are associated. Thus we speak of a transformer with 4 per cent. reactance. In the same sense a reactance for a generator and rated at 10 per cent. is understood to absorb 10 per cent. of the normal voltage when carrying the rated current of the machine.

In the case of busbar reactances each reactance is associated with a section of the busbar and should be rated on the total generator capacity attached to the section, as its current-limiting effect is independent of how that capacity may be subdivided.

For example, in Fig. 5 the generator and transformer reactances are rated 10 per cent. and 4 per cent. respectively on their individual outputs, and the busbar reactance is rated 14 per cent. on a busbar section rating of 40,000 k.v.a. It will be seen that the reactance drop is the same for a fault on either busbar section although the generator capacity

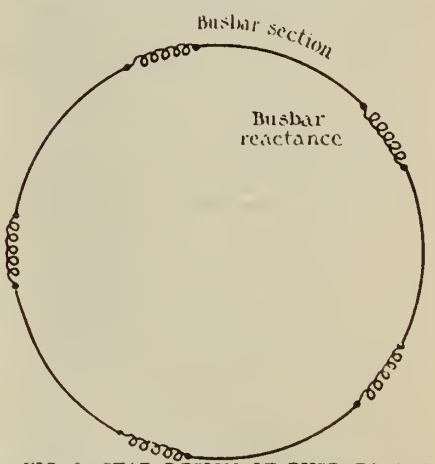

FIG. 9—STAR DESIGN OF BUSBARS AND REACTANCES

on one side is made up of two machines.

A feeder reactance may be rated at 3 per cent. when associated with the feeder, but if its effect on short-circuit is considered in connection with a generating plant of 10 times the feeder rating, it at once becomes 30 per cent. When rated in this way it may be added to the reactance of the generators expressed in the same terms. If, for example, the generator reactance is 10 per cent., the the same terms. If, for example, the tor rating, and limits the maximum short-circuit current to 2½ times the rated output of the generators.

Thus this method of rating enables the employment of reactances to be discussed in general terms and without reference to the size and voltage of the plant.

The current-carrying capacity which may be given to a reactance has no effect on its current-limiting action, and is determined by consideration of the amount of power to be transferred through it.

The actual dimensions of a reactance will, of course, depend both on its ohmic value and on its current capacity, and the individual reactance is best rated in amperes, carrying capacity, and ohms reactance at a given frequency, with the addition of working voltage, the working voltage determining the insulation required.

Arrangement of Busbars

In the provision of busbars and switches, something more is required than a simple straight busbar, or even a single ring busbar with one switch per circuit. Additions are made both to give duplication for safety and to provide flexibility. An extreme is reached by a design like an arc plug-board with provision for coupling any circuit or group of circuits independently to any machine. Such a design has been provided for (proceedings of the Ameri-

can Institute of Electrical Engineers, 1916, vol. 35, p. 886) and gives maximum flexibility with something more than duplication. In a station with 5 machines and 10 feeders, 15 busbars would be required, and 50 oil switches, as against one busbar with 15 oil switches.

The first essential is a spare busbar arranged so that any section can be shut down without interfering with supply. In the matter of switches it is recommended that all normal switching operations should be done by means of oil switches, and that air-break switches should be used only for isolating parts already made dead by oil switches. By this course adequate duplication is provided and the risk of serious trouble due to operator's mistakes in routine work is reduced to a minimum.

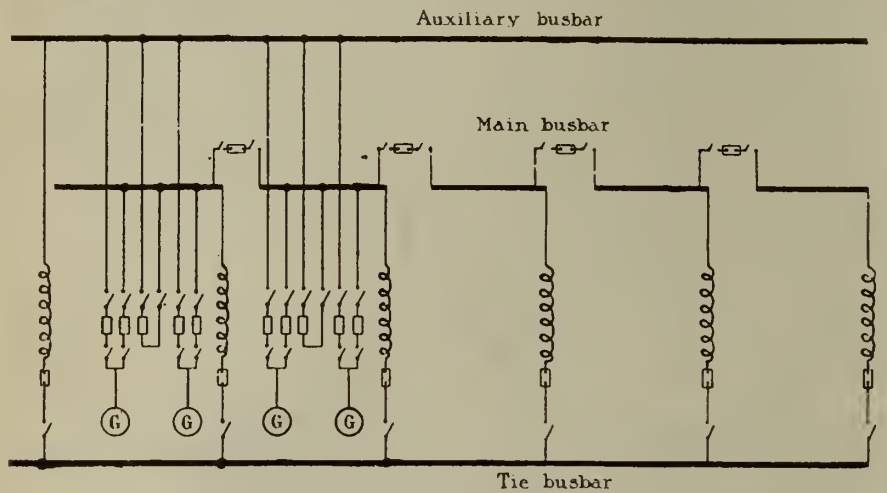

FIG. 11—ARRANGEMENT OF SWITCH GEAR FOR STAR DESIGN.

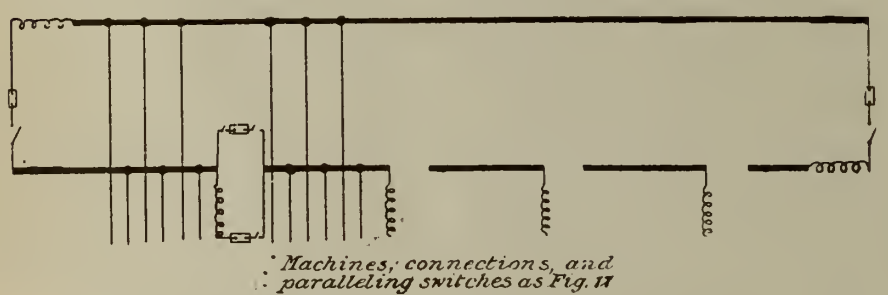

FIG. 12 ARRANGEMENT OF SWITCHGEAR FOR RING DESIGN.

Thus with provision for busbar paralleling and sectionalizing, a station such as described may usefully employ, say, 33 oil switches without reactances (see Fig. 7).

Each addition to the primitive arrangement should be made to give a definite contribution to the results obtainable, and it is a general law of design that there will be increased economy if there is differentiation of function as well. For example, in the illustration given, one of the busbars is regarded as the main busbar and given a section switch. The other is regarded as the stand-by and would be used as a hospital busbar and for testing. The arrangement has all the advantages of a single ring busbar and at the same time provides a stand-by. It does not look like a ring because coupling switches are not shown at the ends, but each section is in fact coupled to both its neighbors, and the paralleling switches are located midway in the length to keep down the cross-section of copper. For the same reason the machine and feeder switches are alternated.

If oil switches are not duplicated, the fact of an oil switch being put out of commission for any reason prevents the corresponding machine or feeder being employed, and thus must lead in the long run to greater expenditure on spare plant or a greater risk of serious lack of spares on emergency.

For this reason large machines should have at least two switches, but on less important circuits a compromise can be effected by employing one automatic oil switch and two inexpensive non-automatic oil-break selector and isolator switches as in Fig. 8, but economy is effected in first cost thereby only where the main oil switches are required to be of large rupturing capacity. It will be understood that the oil-break selector switches will break load current without danger, which an air-break switch would not do.

Arrangement of busbar with reactances.—Busbar reactances may be employed in either of two ways, conveniently described as the star and the ring designs.

In the star design the busbar reactances are paralleled by tying them to a common point or tie busbar as in Fig. 9, whilst in the ring design each busbar section is tied to the next through a reactance, as in Fig. 10.

In introducing reactances, two oil switches will be required with each. One is for paralleling through the reactance and the other for paralleling without the reactance. These switches are so employed that the number of machines tied direct to any group of solidly parallel sections does not exceed the number proper to one section, and is not appreciably less. For example, with two machines per section, two sections should not be solidly paralleled unless at the time they have only one machine running on each. They will be separated by reactance immediately a third machine has been coupled to them. At times of heavy load all the reactances will be in use. At times of light load they will all be short-circuited. This is necessary, for it will be found that with reactances of the ohmic value required it is not always practicable to transfer light load through them without excessive drop of potential.

The complete switchgear in accordance with these recommendations is shown in Figs. 11 and 12, in which the feeders are omitted for simplicity.

It will be seen that, with the five sections shown, six reactances are required in each case. With the star arrangement the sixth is used to tie in the auxiliary busbar. With the ring arrangement a tie is required at both ends so as to ensure a reactance between this busbar and each adjacent busbar. Each arrangement is in effect a six-section busbar.

Each reactance as here shown is associated with a particular busbar to which it is solidly tied, but an isolating switch can be introduced at this point at small cost, giving greater flexibility.

The paralleling switches shown are all essential if duplicate main oil switches are not employed, but where the busbars can be paralleled through one or more pairs of these duplicate switches, the paralleling switches are not essential. The two end one should be retained for uniformity in the equipment for completing the ring main. Their use throughout as shown is recommended, however, as it simplifies and unifies the operations and the amount of thought required.

Advantages of the star arrangement with its extra busbar will be brought out by a study of these diagrams. Whatever sections are employed are paralleled

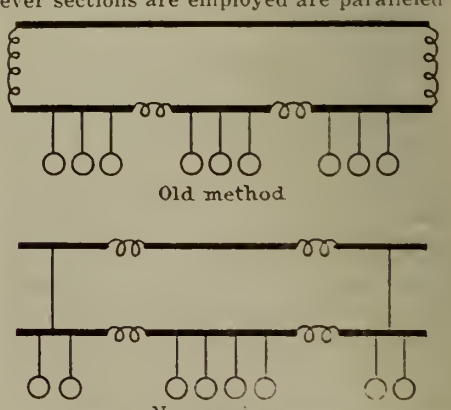

FIG. 13—DISTRIBUTION OF MACHINES IN RING DESIGN

by the simple operation of coupling them to the tie busbar, whereas in the ring arrangement it is not possible to maintain the ring formation when one sec-

tion is shut down, or easy to follow the load-transfer conditions. Mistakes are more easily made which will leave the reactances cut out and too many machines operating in parallel on a section.

The third or tie busbar needs to be at least as well made as the other two, as a fault on that busbar involves all the sections and is fed through all the reactances. It is not duplicated, but may be ringed and broken up with air-break switches. It can be made dead at any time by a temporary sacrifice of economy in running.

There is no doubt, however, on the other hand, that in many situations it is easier to make a good design with two busbars than with three, so that there is a use for the ring arrangement. It will be shown that the load-transfer capacity of the reactances required in the ring arrangement may be as much as that required in the star arrangement, and the ohmic value is doubled for the same protective value, so the k.v.a. rating of reactances for the ring design may be twice that required for the star design and the cost consequently about 50 per cent. higher. This is partly or wholly offset by the omission of the third busbar. The ring arrangement, however, has the defect that under working conditions the ring cannot always be maintained closed. On shutting down any section of the busbar the ring is broken. If the design gives the correct limits with a closed ring it will now be found that there is too much reactance isolating the end sections of the open ring and consequent excessive pressure drop, whilst if the reactances are selected to compromise for this, clearly this can be done only at the expense of the protection afforded. The balance of advantage lies with the star design.

The defect in the ring system can be partly offset by making the end sections 30 to 50 per cent. smaller than the middle section and arranging them as shown in Fig. 13.

To be Continued

LARGE INSTALLATION OF TRANSFORMERS

The Toronto station of the Hydro-Electric Power Commission of Ontario, on Strachan Ave., was originally laid out for two banks of 1,250 kva. transformers with one spare unit, but the load grew so rapidly that in 1913 considerable expansion was required. Accordingly, the station was doubled in length and accommodated three additional banks of 2,500 kva. transformers. In addition to the transformer equipment two new sections of the H4 double bus switch structure were put in commission, serving the 13,200 volt out-going feeders as well as a K 12 remote controlled oil switch structure which served the 2,300 volt load.

Two of the 2,500 kva, banks were installed, but before the last bank was ordered, the decision was reached to again double the unit capacity, and accordingly, fifteen 5,000 kva., 25 cycle 110,000 volt transformers were ordered from the Canadian General Electric Co. This brings the total capacity up to 75,000 kva. on the basis of 40° C. rating of approximately 100,000 kva. on the basis of maximum rating.

To instal these transformers in the original transformer pockets it was necessary to increase the height dimensions very materially.

The transformers are now 24 feet high from the rails to the top of the high tension leass, which accounts for the slim appearance of the tank as shown in the accompanying cut. The floor space limitations also precluded the possibility of using core type construction.

The transformers are shell type units and have reinforced steel plate housings and supports. The economy in weight made possible by this construction, standard with the C. G. E. made it possible and safe to utilize the existing foundations without material change in spite of the fact that the main weight of the transformer is carried over to the central foundation wall by a short cantilever construction.

The transformers have button type spacers between coils and the coil ends extending above and below the core are firmly braced against distortion from short circuit strains. Particular attention is drawn to the appearance of the core shown in the accompanying illustration, which hardly does justice to the unusually fine results obtained in the piling of sheet steel laminations.

The transformers were made at the Peterborough Works of the Canadian General Electric Company and the tanks, which it will be noticed are without horizontal seams, were made at the Davenport Works, Canadian Allis-Chalmers, Ltd.

TRANSFORMER ASSEMBLY. NOTE THE NEAT PILING OF THE LAMINATIONS.

SICILIAN ELECTRICAL COMPANY ENLARGES

A company formed to produce and distribute electricity from water-power in the eastern provinces of Sicily has been so successful even during war times that it recently decided to enlarge so as to include in its scope the entire Island of Sicily, according to the last bulletin issued by the Italian Bureau of Public Information. The "Societa Elettrica delia Sicilia Orientale" was established in 1907, and by 1917 its capital was $3,000,000 and its income $1,000,000. Despite the decrease in industrial development, due to the war, the company was able to declare a dividend of 5 per cent. in 1914-15-16, and in 1917 a dividend of 6 per cent.

The enlarged scope of the company has necessitated an immediate increase in capital to $6,400,000, and by 1919 the company expects to have a capital of $8,000,000.

Fuel Economy is Still Desirable

THE past year has been one of many vicissitudes for the power house engineer, the owner and those having to do with the purchase of power. The coal famine of last winter, with hte resulting tie-up of Canada's industrial life for a short period, will be remembered by all and the conservation campaign waged here to some slight extent, and vigorously in the United States, was the outcome of the necessity for conserving manpower and releasing fuel and energy to the makers of munitions of war.

The lessons learned through this necessity may well be kept in mind during the peaceful days ahead of us. The wise and proper operation of boiler equipment, the success and economy attending upon the use of mechanical stokers and other labor-saving appliances, and above all the absolute necessity for the use of proper boiler room recording and indicating equipment, has time and again been pointed out and should ever be kept before us.

The conservation of fuel is as important for Canada's success in the coming years as it has been for her successful efforts in the past period of strife. This is so for two reasons, the economic struggle for the world's markets, or a proportionate share of them will go to the country which can produce cheaply, and the wasting of a country's natural resources is a thing not likely to be excused for any reason.

Coal is a commodity which once used up can never be replaced except by the substitution of some other source of obtaining heat and energy and the world's supply of coal, while vast in extent, is not by any means everlasting, and at a date measurable in terms of a few hundred years the world will have to turn to some other source. The same is true of fuel oil and other present-day sources of heat and energy such as our at present untouched deposits of peat.

Help This New Feeling Along

THERE is undoubtedly a new feeling arising in regard to the conditions that should exist between capital and labor. In fact, the new feeling is such that it will likely put the boots to that phrase "capital and labor."

It's a poor phrase at best. It draws a line right at the starts that hurts insteads of helps.

It survives the old days when the man in the office looked upon the man in the shop as the human part of the machine.

There has been a wonderful softening influence in the last few days and years.

The son of the man in the shop has gone under in France, and the son of the man in the office marched away and will not return.

The employer who has had much to do with turning out munitions in the last three years in Canada has learned that it is good policy for the people in the shop to make good wages.

An employee who is making good wages is likely to be contented. The employee who is kept down to the lowest possible wage is not going to be contented. He will quit just as soon as the chance comes, or if he stays he will be looking for a chance to strike.

It is only human nature. In these days of living at its highest point, with the purchasing power of a dollar shot to pieces, the man who cannot provide for his home in decency is going to listen hard to the doctrines of Bolshevism. He will become an agitator, whereas decent conditions and a square deal would have made of him a good citizen, and of his home a centre for good influences in the community.

Manufacturers are realizing this point. They are speaking of it openly. They have had a demonstration of the fact that good wages and good conditions will iron out more trouble in the shop than all the deputations and labor departments in the world could ever hope to do.

It is well that this feeling should start now and grow with the new industrial Canada that is coming. Encourage it. See that it gets a chance to develop. It will do more to prevent strikes and lockouts than all the legislation that could ever be piled into the books of the country.

The bigger the margin that can be maintained between the worker and starvation the greater the efficiency of the worker and the success of the concern with which he is connected.

Association and Personal

Walter V. Turner, manager of the engineering department of the Westinghouse Air Brake Company, of Pittsburgh, and an inventor of note, died following a brief illness. Mr. Turner had more than 400 patents granted for various inventions. One of these, the "K" triple valve, is said to be valued at $28,000,000.

George Gray, assistant general manager of the Acadia Coal Company, Halifax, was presented by the company and staff with a chest of silver and an address signed by the executive management and his fellow officials. The occasion was the thirty-fifth anniversary of Mr. Gray's connection with the coal mining industry in Nova Scotia, and particularly with the Acadia Coal Company.

G. H. Duggan has been appointed to the presidency of the Dominion Bridge Co., to fill the vacancy created by the retirement of Phelps Johnson, the former president. Mr. Duggan has had a long service with the company, and for the past several years has acted in the capacity of vice-president and managing director, and has been closely associated with most of the important developments and extension of the Dominion Bridge Co. Mr. Johnson will remain on the board of directors of the Bridge Co., and will also serve on the executive committee.

William J. Galbraith, a well known Montreal civil engineer, died at his residence, 4145 Dorchester street, Westmount, on Dec. 21st from pneumonia. The deceased gentleman, who was only 32 years of age, had enjoyed a very successful engineering career. He graduated from McGill in 1909, and at the beginning of 1910, was engaged in the Rocky Mountains with the Geological Survey, and in the fall of the same year, he entered the firm of M. P. & J. T. Davis, as assistant engineer on caisson work for the Quebec bridge, remaining there till the spring of 1912. He then started in construction work for himself, and carried out many important works for the Dominion Government. At the outbreak of war he entered the Foundation Company of New York as superintendent of construction, in which position he remained until his death. He was a member of the British Institute of Civil Engineers, and leaves a widow and one daughter.

Major F. L. C. Bond has been appointed chief engineer of the Grand Trunk Railway system with headquarters at Montreal.

Lieut. Lloyd M. Archibald of the Royal Flying Corps, well-known representative of the Dart Union Company of Toronto, as he appeared as a prisoner of war in Germany (on the right). Word has just been received by his brother, Charles P. Archibald, of Charles P. Archibald & Co., machinery dealers, Montreal, announcing his safe arrival in England after being a prisoner in Germany for over a year.

Major Bond, who succeeds Mr. H. R. Safford, recently appointed engineering assistant to the regional director of the central western district, United States railroad administration, has just returned from overseas after two years' service with the 10th Battalion Canadian Railway Troops. He was born in Montreal in 1877. He was educated at Montreal High School, the Collegiate Institute and McGill University. Upon graduating from McGill in 1898, he entered the service of the Grand Thunk as assistant resident engineer of the eastern division, and in 1901 was appointed engineer in charge of double track construction. In 1902 he was night superintendent on the construction of the Park Avenue tunnel of the New York subway, but returned to the Grand Trunk as resident engineer, eastern division, a position which he held until 1913. From 1913 to 1916, when he went overseas, Major Bond was division engineer, eastern lines. He holds a high reputation in railway and engineering circles and his work with the Canadian expeditionary force won the highest commendation.

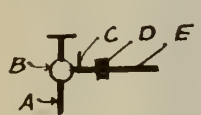
The Operators' Point of View

PROTECTING HEATING PLANTS FROM FROST

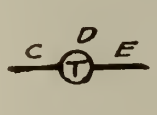
By J. E. McCORMICK

DURING the cold winter months the chances of a pipe or valve being burst by frost are remote indeed in those plants which are used entirely for heating dwellings or for heating shops which contain goods or merchandise of such a nature as to become damaged even by slight freezing, but in isolated steam plants (and there are many of them throughout the country), used for mill or factory power, but not for heating dwellings, and which are therefore idle from Saturday noon or night until Monday morning, as well as during fourteen to sixteen hours out of every twenty-four during the week, the engineer must be more or less on guard against damage by frost, especially when the thermometer outside stands at many degrees below zero for a time, as is often the case in many Canadian localities.

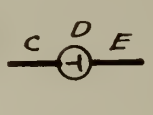
There is also more or less chance of frost doing damage in those plants which, in addition to furnishing power, are used for heating shops or factories during working hours, the steam being shut off from the heaters and radiators during nights and Sundays. In such plants I have found the steam lines to be much more liable to damage than the water lines are. The water lines are shorter, and good insulation by means of some kind of covering will do much to protect them and they can generally be so planned that those which must necessarily contain water may, when they do get cold, or nearly so, be warmed up again by opening slightly the necessary valves and allowing water to flow slowly through them from towards the boiler for a little while. This will warm them up and leave them full of hot water again. A slight leakage through the lines, a drop or two per minute if otherwise permissible, will sometimes aid in maintaining the temperature of covered pipes.



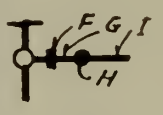
1



2



3



4

But with steam lines it is different. According as the boiler cools down and the pressure goes off, the steam in the lines condenses. Generally a little leakage in the valves allows the most of this condensation to escape, and the remainder freezes in the lines in the form of a shelly ice or of a hoar frost. This is in lines not long enough to require to be trapped. My experience with such plants leads me to believe that except in exceptionally cold weather, covered pipes will not burst with this shell ice, and so long as the boiler is not fired enough at a time to raise any steam, and more especially if the accumulating air pressure caused in the boiler by expansion of the water, while heating, is allowed to escape through the upper gauge cock or other vent while the water is heating, said vent being closed again when the fire has been banked; then the boiler and the water pipes may be kept warm for days without danger of damage to the steam lines. If, however, any steam is raised, it is, in most of these layouts, imperative that enough be raised to thaw out all the steam pipes containing any of the shell ice and that care be taken to see that they are thawed out. I generally find that it is at the valves that the ice seal is most apt to exist and that some hot water poured over the body of these will thaw them enough to open, and this will allow steam to flow, which will soon thaw the intervening pipes. If steam is raised without the lines becoming thawed out before the steam goes off again water will form in the steam pipes and will flow into the spaces in the shell ice already existing and fill these spaces up; then, when this freezes, something is almost certain to burst. Of course if the valves next the boiler were absolutely steam tight no steam could enter the lines to condense them and do damage, but this ideal condition cannot be fully maintained without undue expense for renewal of valves and parts, hence, in general, the principle applies. I have several times known steam lines to suffer damage in this way and had similar experiences myself in plants I had charge of before I learned the real cause and its cure. It is noteworthy that in each of these instances the water lines remained intact.

And now for a simple remedy, which obviously does not consist of maintaining a constant steam pressure on the lines, thus involving excessive standby consumption of fuel if kept up during all holidays. The instance sketched is for taking steam direct from the top of the dome or boiler if desired, but the principle can be applied to other positions. In Fig. 1, A is the upright nipple, B is an angle valve, C is another nipple, D is a three-way stop-cock, and E is the continuation of the line. The side outlet of the three-way cock opens to the atmosphere. In operation—during the time the line is in use, the stop-cock is turned to let steam pass directly through it into the line (Fig. 2). When steam is turned off the line by means of the angle valve B, the stop D is turned so as to give a free passage from B to the atmosphere (Fig. 3) and the line is also drained. Now any further escape of steam from the valve B passes out through the side outlet of D into the atmosphere and escapes instead of entering the line to condense and do harm. Any drip from the side outlet of the stop-cock D can be carried away by means of a neat metal trough. Fig. 4 indicates an arrangement calling for more parts but which may be preferred by or be more easily available to some. A, B, and C are as before; F is a tee; D is nipple, H is a globe valve, and I is the continuation of the line. The tee F is supplied with a nipple and a globe valve to provide an escape for leaking steam when B and H are closed. Perhaps quite a number of engineers can benefit as much by the use of this device this winter as I could have benefited years sooner had I known of it and its advantages then.

CARBON AND COMMUTATOR WEAR

R. E. HELLMUND,
Westinghouse Electric and Manufacturing Company

Carbon manufacturers, as well as manufacturers of dynamo electric machinery, have made numerous tests to determine contact resistances, friction losses, etc., of various carbons. While such tests are of interest, they contribute very little towards the real practical need; namely, a carbon which can stand high current densities and high sparking voltages with small wear.

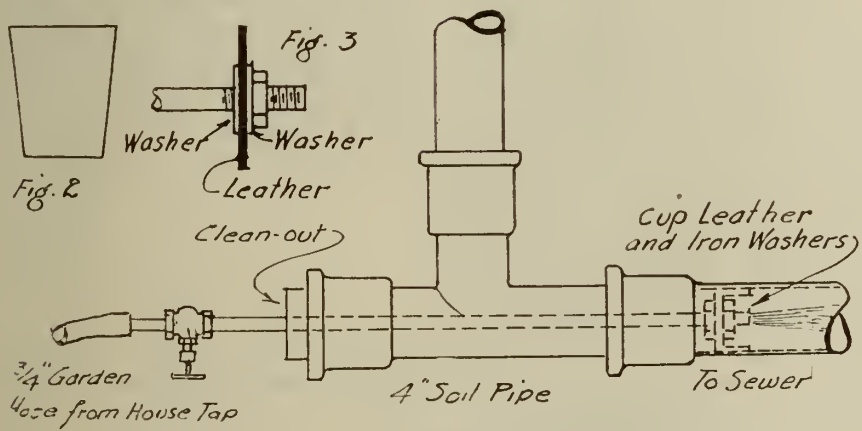
In order to develop such carbons, it would seem essential to first make tests determining how the carbon wear is affected by current density, sparking voltage and peripheral speed. Present indications are that with many commercial carbons very appreciable densities can be used if there is no sparking voltage, while sparking voltages up to 15 or even 20 volts across the brush cause very little wear at certain speeds, if the current density is low enough.

More data along this line should be of great advantage both to the carbon manufacturer and the designing engineer.

CLEANING SEWER

By J. E. NOBLE

A few days ago I was watching a plumber trying to clear an obstruction from a 4-inch sewer pipe. His method was to run the end of a hose into the end tee, after removing the clean-out cover, and plugging rags or clothes around the hose to prevent the water backing out. Why will men use such crude methods when a few minutes' work will supply them with a really good tool for this style of a job? An idea of the tool can be formed by a glance at the sketch; I used this tool with fine success when I worked at the plumbing business as long as twenty years ago (perhaps I should use modern terms and call it sanitary engineering, but from personal observation the old plumber is "in it" to the neck with the sanitary engineer, in numerous cases at least). It is nothing more or less than a cup leather held on the end of a piece of ¾-inch iron pipe by two iron threaded washers, the other end of the pipe being attached to a hose, which in turn is coupled to one of the house taps. A valve can be placed on the end of the pipe so that the flow of the water can be controlled without going to the other tap. To make cup leathers, form a piece of sheet tin or galvanized iron in the form shown at Fig. 2, size on top 6½ inches, bottom 4 inches; this will do for cup leathers 6 in. to 4 in. To make the cup, cut the leather 2 in. over the size required; that is, for a 4 in. cup make the leather size 6 in. Now place the leather between two iron washers and bolt them together as in Fig. 3. Next, place it in a dish of warm (not hot) water for a few minutes, this will soften up the leather. Next remove from the water and force down into the form, Fig. 2 and leave there for half an hour or so until the leather gets time to set into shape. This makes as good a cup leather as can be bought. Of course judgment must be used in picking your leather; use a piece of firm, flexible leather, sole leather is too hard, and belly leather too soft; use side leather.



ARRANGEMENT USED IN CLEANING OUT OBSTRUCTED SEWER.

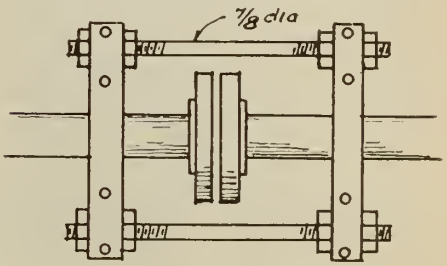
MAKING HARD GASKETS DO THE JOB

Some time ago we got some of the "moulded" black rubber gaskets for hand holes. Owing to a certain amount of unevenness in the metal surfaces these were required to come to a fit by being screwed up tight enough to force the highest spots to imbed themselves in the gaskets. This particular lot of gaskets were particularly hard, and it was found difficult to get them tight enough without danger of stripping the bolt threads. These gaskets would even break by bending them back and forth for a while, and for a time they lay discarded and supposed to be useless. Finally it was found that they would soften in hot water, so next time one was needed it was placed in hot water just before required; then, when soft, was taken out, put in place and the nut screwed up quickly, before the gasket had time to cool. They are all used up now but one and there has been no trouble with them since the hot water cure was adopted. Heating the hand hole cover thus as well as the gasket, retards the cooling action while putting in place and gives a little longer time to work without the gasket becoming too cool. The pressure carried on the boiler was from 90 to 110 lbs. per sq. in.—J. E. M.

RENEWING WORN GASKETS IN LARGE FLANGE JOINTS

By S. E. Burd

It is a matter of some difficulty at times to renew joints in large pipe, especially in tight corners where space is limited. As will be seen from the illustration, four pieces of heavy flat iron are shaped to fit around the pipe as shown in the illustration and each pair are clamped on the pipe by ¾ in. bolts. These bolts have 15-16 in. fillers threaded on them so that the ⅞ in. rods will be an easy fit. The ⅞ in. rods are inserted while the fixture is being placed



on the pipe and the nuts between the clamps are then screwed up. This forces the flanges apart to the proper distance and the new gasket can then be inserted easily.

After the gasket is in place, if there is no spring in the pipe the inside nuts can be slacked off and the flanges pulled together again by the outside nuts.

After making this outfit it only takes one man a short time to repair a leaky joint. It can be used for different size pipes by putting packing between clamp and pipe within reason.

HOW I BROKE INTO PRINT

By D. A. HAMPSON

Under that none-too-elegant title we would expect to find a ten cent "work" for the instruction of budding authors, shelved beside the other "how" books in our news stands and book stores. So far as trade and business paper writing is concerned, there is no "how" to it at all—it is simply a case of Do and Do Again.

Right here in POWER HOUSE we see appeal after appeal to the men on the firing line to open up and share the interesting experiences and the trade kinks that they have met with in their work. Whenever two or three mechanics get together one of the subjects of conversation is how they did this difficult job without the proper tool or how the boss in their shop discovered a new, quicker way of doing a time-honored piece of work. And these mechanics are just as bad as so many women—they can't wait for one to finish to get in another experience equally as good or better—if nothing prevented, they could and would talk a whole day without exhausting the subject.

These are the experiences the editor wants. Write them just as you would tell them—the editors will smooth off the rough edges and put on the polish if which may be common property of the needed. The very methods and tools shops in your vicinity may be unknown elsewhere and local pride, if nothing more, should want to put that vicinity on the map and bring it that much credit

for mechanical initiative. Over and over again some acquaintance has told me of reading something of mine in a certain paper; invariably my reply has been, "Yes," but, Will, you have been so much farther than I and have had such varied experiences that you should have material for a year's writing, all of it being more valuable than mine."

Those people who have such goods to sell—and it's a selling proposition—rarely get down to the point of actually trying, or if they do try once and get turned down by an editor, they become disgusted, like the Grouch that complained in a recent issue. Why, one of the standing jokes in our household was for me to be met at the door with, "You've got another R. M." R. M. standing for returned manuscript, a highbrow name for what was often but half a sheet of paper.

There are articles that lack merit and subjects that are hackneyed, but anyone who reads the paper he expects to contribute to can select an experience or two which steer clear of these dead lines. And then the old matter has to be brought up ever so often for the benefit of the younger generations in the trade. Basic principles and operations remain the same for long, long years, and will bear repeating at intervals, for all technical papers strive to educate the newcomers as well as the older men. These basic operations are subject to new and ingenious applications with the modern advances in the art. All of these things can be worked into articles that the editor is glad to receive.

Two of us as apprentices subscribed to POWER HOUSE. We found a world of information in it to discuss and compare—I'm afraid often on the shop's time, but then we were pushers and ready to try anything new or quicker for the shop. Sometimes we had a job to do that seemed as goo das those we read about and naturally one of us remarked, "Let's send it to POWER HOUSE." That got to be a joke, but finally I took a picture of a planer job that turned out well and wrote a couple of hundred words about it and sent it to the editors without saying anything around the shop. When that appeared in print and I showed the cheque for four dollars that went with it, the idea ceased to be a joke any longer. Following that first successful instance, there was a long list of rejected "articles" and a few money orders for fifty cents, but the editors were courteous and the rejections only served to spur on to better efforts—to be frankly critical of one's own work is the first step toward success.

And it pays the author in every way. The Buick Six that serves as a splendid refresher after a long day inside could be bought with the money received from writing and its maintenance and that of the cars I have owned before more than covered by the same source. And then there is the self-improvement side of writing—"writing makes a ready man," and as he writes he is sure to stumble on points of doubt upon which he must read up before he turns out the completed article. Often a single point entails many evenings of study, to the ultimate good of the student. Then anything that is written fixes itself much more firmly in the mind than what is simply read. All of these things help the writer as much or more than the ones who read them and have a distinct broadening effect. Added to the foregoing is the fact that some one is waiting for what you write—glad to read it, and some one else is ready to pay for it at substantial rates.

TEMPORARY REPAIR OF A BROKEN STOP VALVE

By T. H. F.

AN interesting repair of a bad break came under my observation when sailing as 3rd engineer of "S.S.———." We were bound from Cardiff to Nagasaki, Japan, though as we were carrying Welsh coal for the Japanese navy, and Japan then being at war with Russia, our ostensible destination was Shanghai for orders. However, we had come down the Red Sea with its usual discomforts, across the Indian Ocean, and were making up for Colombo to coal. We sighted the harbour about 7 a.m., and about 7.30 the first officer gave orders to the bo'sun to get steam on the windlass, preparatory to anchoring. Now the bo-sun had sailed in steamers so long that he was, in his own mind, something of an engineer. Therefore, instead of notifying the engineer on watch that steam was wanted on deck, he undertook to put steam on himself. The two valves controlling steam to the fore and aft deck were situated in the fidley, at the bridge deck, and easy of access to anyone. The gallant bo'sun, whose engineering knowledge really was all comprised in the ability to turn a wheel to the right or left, which would open or shut a valve, naturally never thought of the fact that the steam had not been on the deck pipes since leaving Suez, so he stepped into the fidley, took the wheel in his tarry hands, gave it a mighty twist, and then things happened. It was here that the chain of events reached me personally. The messroom steward had just entered my room to call me, and I was sitting on the edge of my bunk, rubbing the sleep from my eyes, when a terrific report, followed by the roar of escaping steam burst on my ears. I jumped from the bunk into my engine-room slippers, and in pyjamas and slippers, made for the engine-room. After the first shock my ear could still distinguish the beat of the engines, and there was no sign of steam in the engine-room. Going on the top grating I opened the door leading to the boiler tops, but though the noise was plainer here, there was no steam. As I turned back again, the second came up from below, and made toward the door, beckoning me to follow. He went to the auxiliary stop valve on the port boiler and motioned me to the starboard boiler. These were shut off, and quietness reigned once more. This sounds simple, but any of my readers who have gone on boiler tops in tropical weather clad in pyjamas and slippers will appreciate the pleasure of it. As we came out onto the top grating again, I asked the second what was damaged, and elicited at first a very complete and highly ornamental biography of our bo'sun, bo'suns in general, deck officers and skippers, winding up with the announcement that the donkey boiler stop valve had been blown off. This was the case.

Steam for the winches and windlass was taken from the main boilers, through a reducing valve, and from the donkey boiler. The pipe from the reducing valve joined the donkey boiler pipe close to the valves controlling the deck steam. The donkey boiler was situated on the main deck, and from the donkey boiler stop valve to the bridge deck where controlling valves were situated, was about 30 feet in length, with a rise of about 3 feet. Now it was the practice to leave steam when at sea,

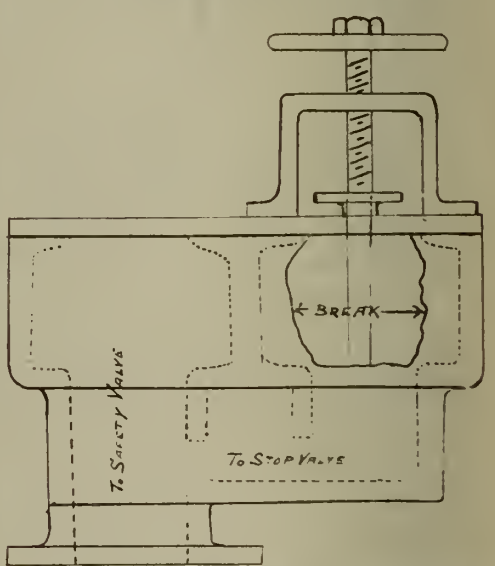


FIG. 1—SHOWING BREAK IN STOP VALVE WALL.

open on the main boilers to the reducing valve, and up to the fidley, so that if steam was needed on deck, it could be opened without anyone having to go on the boiler tops. As no one but an engineer was supposed to touch the valves on deck, there was no danger. When the bo'sun threw open the valve a slug of water started off, and the first obstacle it struck was the donkey boiler stop valve, which surrendered. The stop valve was contained in the same casting as the safety valve, which made it more awkward. The first thing to be done was to blank the pipe off between the donkey boiler and the supply from the reducing valve, so that steam could be put on deck to handle the anchor in Colombo. This little job being done, a

hurried visit to the messroom was paid, where the dried up remains of breakfast were bolted just as the stand-by rang for the pilot. This was the beginning of a perfect day, the remainder being spent between tallying coal and doing little jobs in the engine-room, such as packing the H.P. gland, etc., with the sweat forming pools wherever one stood. The delights of a coaling port ending like anything else, we were under way again about 8 p.m. with the next stop Singapore.

Next morning after breakfast, the chief, second and myself went forth to inspect the damage, and see what could be done. It was essential to have the donkey boiler at work in port, so that the main boilers could be cleaned. The side of the stop valve wall had been blown clean out as shewn by the sketch, but the lower port and safety valves were intact. The cover was good, and the valve itself not damaged. The first thing suggesting itself was to make a patch out of some plate we had, ¾-inch thick, but upon going further into the matter found this would be a job of some considerable magnitude, and other means were looked for. It was finally decided not to attempt a patch, but to use a temporary expedient that would serve till we arrived at a home port, where we could get a new casting. Looking through the stores we found a cop-

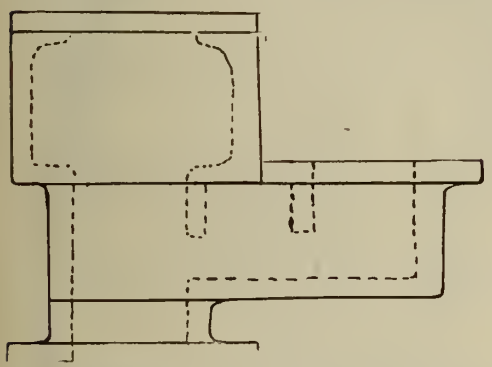

FIG. 2—SHOWS STOP VALVE BOX WELL CUT AWAY TO RECEIVE FLANGE.

per bend 90°, with flanges each end. This was the right size, 4 inches, if I remember rightly. The whole casting was taken from the donkey boiler top and lowered down the fidley, and taken to the engine-room vice bench. The broken wall of the stop valve was drilled all round and cut off with a chisel, leaving a flat face. The seat of the stop valve was drawn out, and holes drilled for studs to fit the copper flange. Of course, this took time, as it had to be done by the engineers in the course of their watch off. However, it was finally completed, and the casting replaced. The bend being bolted on to the casting its vertical flange came in approximately the same position as the stop valve flange had been, and the pipe was connected up with a blank flange in between. The method of working was as follows; On arriving in port the steam for the winches would be used from the main boilers during the remainder of the day of arrival. When cargo working for the day was finished, steam was shut off from the main boilers, the blank flange was removed and the donkey boiler lit up, steam being ready for the morning. When getting ready for leaving the modus operandi was reversed. The main boilers would be, of course, lit up and steaming and when cargo was finished the donkey boiler was blown down, the blank flange put in again, and steam opened up from the main boilers. By this means there were no delays, and the time of putting in and removing the blank was about 10 minutes. As we called and worked cargo at Moji, Hong Kong, Moulmein, Fiume, Aggiamarina, Tripoli, Tunis, Tarbis, Holmis, before we arrived at Antwerp, some months later, where our casting was awaiting us, we got quite used to the blank flange drill, and somewhat missed it after the new casting was placed.

A DIAGRAM DETERMINING THE COST OF COAL FOR GENERATING STEAM

The accompanying diagram furnishes the power plant operator accurate information on the cost of coal for generating steam. Knowing the price and the amount of coal burned and the quantity of water evaporated, the solution is easy. Start with the cost of coal per ton and project vertically, intersecting the oblique line corresponding to the evaporation from and at 212 degrees Fahr. being obtained from the boilers, then move horizontally to the left margin, where the cost of coal to evaporate one thousand pounds of water from and at 212 degrees Fahr. is given. The chart can also be used to determine the evaporation required to generate steam at a certain cost, by reversing the above process. This chart should awaken interest in the relative efficiency of a mechanical stoker as compared with hand firing. The stoker shown in the illustration attacks Mr. Wasted Fuel from the following angles:

1. Smokeless combustion and a high percentage of CO^2.

2. Volatile substances in the coal are distilled before they are introduced to the incandescent fuel bed.

3. A forced draft system of air control supplies the correct amount of air mixture at all times.

4. Carbon often wasted in the ash is burned before dropping the dumping grates.

GETTING A REAL DRAFT

A good draft is one of the most essential things about a boiler plant, and special attention should therefore be paid to it when the plant is laid out. It is easy to cut the draft down if it is too strong, but if it is too feeble the owner of the boiler is faced by a serious situation. The value of a powerful draft is particularly appreciated when some emergency makes it necessary to force the boilers beyond their normal capacity for a time. A strong draft also makes it feasible to burn relatively cheap and low grade fuels.

TRADE GOSSIP

New Pulp Mill for Chicoutimi—The Price Bros. Ltd. are about to construct a large pulp mill at Chicoutimi, on the Saguenay River, a few miles west of the village. Power for the new mill will be obtained from the Shipsaw River.

Tottenham, Ont., has recently passed a by-law for the establishment of a commission for the administration of all works undertaken by the corporation for the distribution and supply of electrical energy consequent upon the contract entered into with the Hydro-Electric Power Commission of Ontario. A vote will be taken in January for the election of two of the members of the Commission.

London Saves Money—The general manager of the Hydro-Electric Power Department of London in his report shows that London saved about $15,000 by the enforcement of the power conservation regulations during the past year. The normal peak load of 10,000 horsepower was cut to 8,000 horse-power, but since the signing of the armistice the 10,000 is again being used.

London, Ont.—Although the power load, raising all week, reached the 10,000 horse power mark, no harsh measures were adopted by the Hydro-Electric Power Commission. The city thus reached practically its pre-war consumption, and this would appear as though the falling off of munition-making load had largely relieved the power shortage that has existed for so long.

Ottawa.—No less a sum than $1,100,000,000 has been expended by Imperial Munitions Board during the war, and 75 per cent. of this amount has been spent in Canada. The board still has the plants which it has erected in its own name, and these will be most likely disposed of to private manufacturers and adapted to the needs of peace industries. With the exception of selling these plants the board's business is practically wound up.

Coal Production in B.C.—A decrease in production of coal in British Columbia during November amounted to approximately 49,476 tons, as compared with the October total. The falling off is attributed chiefly to the lower output of the Island collieries, caused principally by the Spanish influenza epidemic. November production is estimated at 168,006 tons, as against 217,482 tons for October. For the eleven months ending November production in British Columbia amounts to 2,372,161 tons, which is 222,186 above the 1917 record.

Government Announcement. — Additions to federal buildings throughout the country, which had been planned before the war, will soon be started, according to an announcement from Ottawa. The Government bought, just before the war, property on the northwest corner of John and Main street in Hamilton, for an addition to the Custom House, and it is surmised this work will be included in the work mentioned in the announcement.

Promoting Empire Trade.—Measures are being taken by the "Bulletin" of the Imperial Institute to familiarize tanners in the British Empire with the good qualities of the Indian hides. Before the war these hides were collected by German agents and were exported principally to German tanneries. Investigation has been made regarding the possibility of finding British markets for the Indian raw materials, and information is given out to the representatives of the leather industry so that this trade can be kept within the Empire when normal conditions are restored.

Chemical Director Talks—The director of the Chemical Division of the War Industries Board of the United States, Mr. C. H. McDowell, has recently revealed the reason why American farmers received only 66,778 tons of nitrates instead of 100,000 tons through the $10,000,000 appropriation made by Congress. The remaining 42,000 tons were commandeered by the War Department when the German drive became a menace last spring. Military necessity has kept the details a secret hitherto, but it can be told now that the sacrifice of the fertilizer made possible a much greater supply of explosives.

Hamilton's Output.—Hamilton munition plants turned out 3,471,425 shells during the war for the allied forces. The largest output of individual shells was that of the Dominion Steel Foundries, which turned out 1,316,430 18-pounder shrapnel shells. The heaviest shells manufactured here were the 60-pounder high-explosive shells, manufactured by the Canadian Westinghouse. Limited, and the Sawyer-Massey Company. Nine local plants turned out 18-pounders, the production of which far exceeded that of any other kinds. Manufacture of munitions in Hamilton began in 1915 and ceased in December, 1918.

London, Eng.—Lloyd Harris is visiting the Continent to look over the situation in Belgium and France and to confer with the Governments of those countries. Large supplies of all kinds are needed for rebuilding in the ruined areas and for equipping national industries, and there is sound ground for expecting that a considerable proportion of these goods will be bought in Canada, the Government in each case being the purchaser and assuming responsibility for all payments. There would appear to be openings for Canadian trade in the Balkans and Roumania. As for trade generally between Canada and Great Britain there

CONDENSED ADVERTISEMENTS

SALES ENGINEER—PRACTICAL OR TECHnical engineer as salesman for high grade line of power plant equipment by largest concern of its kind in the country. Most unusual opportunity. Prefer man who has established a sales record, but will consider one without experience, provided he is properly qualified. Give details and record of last three positions held and salary expected to start. Box 151, Power House.

WANTED—BOILER ROOM ENGINEER, FAmiliar with modern methods of boiler room operation and capable of using instruments for testing. Location western Ontario. None but first-class men need apply. Box 150, Power House.

is every indication that it will develop rapidly on normal business lines once restrictions upon imports are removed.

Halifax.—During the fall of a very high tide about a month ago the electric welding tug "Albert C.," owned by the St. Lawrence Welding Co., was caught on a wharf and tipping over, sank. The method used in raising her was rather ingenious. After the water had been pumped out several times and she had been raised to the surface only to sink again on account of the tackle with which she was held, slipping, she was finally dragged up on the Dartmouth beach at high tide by means of cables passed around her by divers. When the tide went down and left her high and dry she was pumped out. The work was done by Beazley Bros. It was found that the apparatus aboard her will have to be scrapped. However, a new plant from Montreal is now in Halifax ready to be put aboard. The air compressors and auxiliary machinery suffered little or no damage and the hull and engines are in excellent condition. A large gang of workmen are now at work building the new housing which will be ready in about a week. The St. Lawrence Welding Co. have secured a site on one of the central wharfs in Halifax and will move into their new shops in about ten days. A complete staff has been secured and a competent foreman superintendent from Montreal will arrive in the city shortly to take charge. Managing Director A. M. Barry has been in the city for the past month directing the removal from the Dartmouth side to the Halifax shops.

CATALOGUES

The Link Belt Co., Toronto, have issued a catalogue on the equipment for the handling and separation of coal at the mine. Their long connection with this business has enabled them to specialize in the equipment for the handling, separation and loading of coal at the mines. The catalogue shows the various types of coal-handling equipment made by the company and shows many complete installations that they have installed in the past. Eighteen pages are devoted to illustrations showing various coal tipples and loading chutes of various coal companies. The illustrations of complete equipment are followed by detail pictures, which show to good advantage the various types of conveying, sorting and cleaning apparatus. Box car loaders are shown, coal feeders and continuous centrifugal driers are illustrated.

The Link-Belt Company, Toronto, has issued a new booklet entitled "The Economical Handling of Coal and Ashes and Reserve Coal Storage." This book from the wealth of details and the illustrations it contains is a valuable reference work on the subject. The modern power plant contains much equipment which is the result of real engineering genius, but it is only recently that the boiler-room has begun to receive the attention which it deserves. The development of the electric generator, the steam turbine and its various accessories has proved a greater attraction to inventive genius than the more prosaic problems of fuel saving and labor saving in the boiler-room. As a matter of fact, however, boiler-room savings probably offer greater possibilities than further savings in the generator room. Many of the large power plants are built by corporations employing competent engineers, who are familiar with the best modern practice, and who obtain the co-operation of specialists in selecting and arranging the various parts of the equipment. In many of the smaller plants, however, the owner is apt to rely largely on his own judgment or on the judgment of an architect or engineer whose experience is not broad enough to ensure the best results. To both of these classes of power plant owners the subject matter of this book should prove of unusual interest, as it brings together in a compact form the various systems and devices used for the handling of fuel and ashes. The various types of equipment manufactured by the company are shown and power plant layouts are in all cases given, so that various arrangements of the conveying equipment may be readily seen and understood. The Peck carrier, belt, conveyers, scraper conveyers, and other forms of conveying apparatus are described in detail and weighing devices, measuring apparatus and other apparatus which goes to make up a complete coal and ash handling plant are described and illustrated.

STARRETT BOOK IN ITS FOURTH EDITION

The fourth edition of the Starrett Book for Machinists' Apprentices, published by the L. S. Starrett Co., of Athol, Mass., has just been issued. The book, now in its thirty-fifth thousand, is a well illustrated volume of 176 pages, bound in red Athol leather and designed to answer in an authoritative manner questions as to how to do the every-day work of the average machine shop. The different classes of work are taken up separately, the most common errors pointed out and the correct practice indicated. Much attention is given to the proper use and care of tools, the reading of micrometers and verniers, bench work, lathes and lathe tools, grinding, belts, gears, etc. The book is essentially for the apprentice rather than the expert machinist, though the latter will find much of interest and value, and is intended to provide the answers to the many questions usually asked of the foreman or superintendent. Distribution is being made exclusively through the hardware dealers handling the Starrett line of tools, the price being 50 cents per copy. The briefest examination of the volume will convince the ambitious apprentice or machinist of its value in his every-day work.

NON-CORROSIVE
CYLINDER OIL
MANUFACTURED ONLY BY
E. H. KELLOGG & CO.
NOS. 242 & 244 SOUTH ST. NEW YORK, U.S.A.
FRICTION LOSS

An overload is often a necessity. But it is hard on an engine. To successfully carry an overload so that there will be no after effects on the engine a very careful selection of your oil should be made. An oil that is not free from impurities will cause a greater wearing on the bearings, a great friction loss will occur. You will need to fire the boiler more often because the engine will be harder to run. In this manner you lose out. You work harder, have larger operating costs, and less power all because of your oil. Do as a great many Canadian engineers have done—give Kellogg's "Non-Corrosive Cylinder Oil" a trial. Absolutely pure. Write us regarding it.

STEAM TRAP

The Steam Trap SARCO is the only steam trap of the expansion type that can be used for any given pressure from 0 to 200 lbs. For pressures above 30 lbs., it is the only substitute for heavy, cumbersome and expensive bucket or float traps.

The enormously increasing use of the SARCO is changing engineering practice everywhere. It is no longer necessary to install long return lines to a distant trap. The price and the size of the SARCO permit its use at every point that needs trapping and where it is used you have no live steam in your returns. This means smaller return lines and saving of the steam that long lines waste constantly.

Just as modern heating demands separate trapping of radiators, so modern steamfitting demands separate trapping of machines and coils. It is the SARCO that permits it, whether your pressure is 2 lbs. or 200 lbs.

Figure it out yourself. The SARCO is efficient and its cheapness is due to the plain fact that its novel principle enables a simpler, smaller mechanism to do the work of the older devices it supplants.

Remember, it is made in all sizes from ¾" to 3" and will be supplied on 30 days' unconditional trial. You cannot afford to say you don't know the SARCO, when it costs you nothing to try it.

Forgetting

One of the things we all do well is to forget.

Names that were household words yesterday are gone to-day.

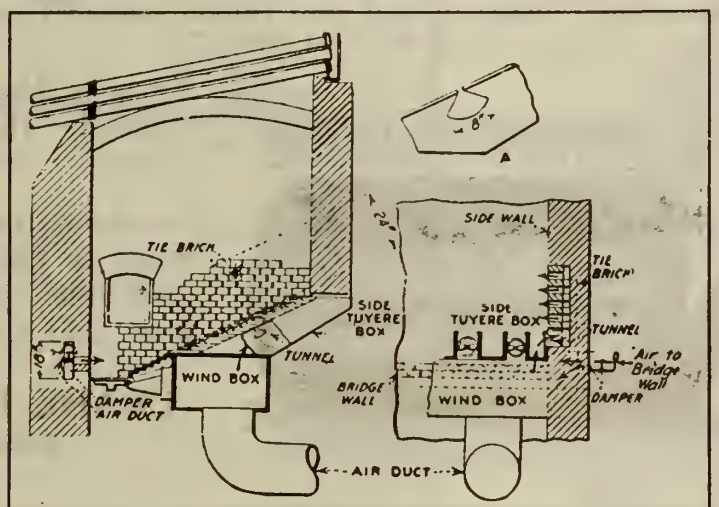
Because people knew your Name and your Line a year ago it is no sign they do to-day. They forget easily.

Keep yourself in the public mind by advertising. It is just as important to make old friends remember as it is to win new friends. Advertising does both.

Add Power To Your Furnace

by eliminating the fuel-waste resulting from the "freezing" of clinkers to the side walls. The Bernitz Method of constructing side walls with interior air passages through which cooling air currents are passed to keep the bricks below the fusing point will

Positively Prevent the Accumulation of Clinker Mass



The Bernitz System as applied in a Taylor Stoker Installation

The Bernitz Method

1. Saves coal by insuring more perfect combustion of the fuel used.
2. Increases boiler efficiency by shortening time spent in cleaning walls.
3. Increases efficiency by burning coal which formerly clinkered.
4. By shortening time spent in cleaning walls reduces influx of air through doors.
5. Saves B.t.u.'s usually lost by radiation through side walls.
6. Permits increased forcing of fires by eliminating danger of clinker "freezing."
7. Makes it possible to remove such clinkers as are formed without dumping fire.
8. By reducing manual labor in boiler room keeps laborers more contented.
9. By keeping fires clean insures greater uniformity in heat applied.
10. Is equally applicable to old or new constructions.

The Bernitz Method is licensed, not sold. It has received full patent protection in Canada and the United States and in foreign countries, and licenses under these patents are being granted on the basis of the H.P. rating of the boilers under which the Method is to be installed.

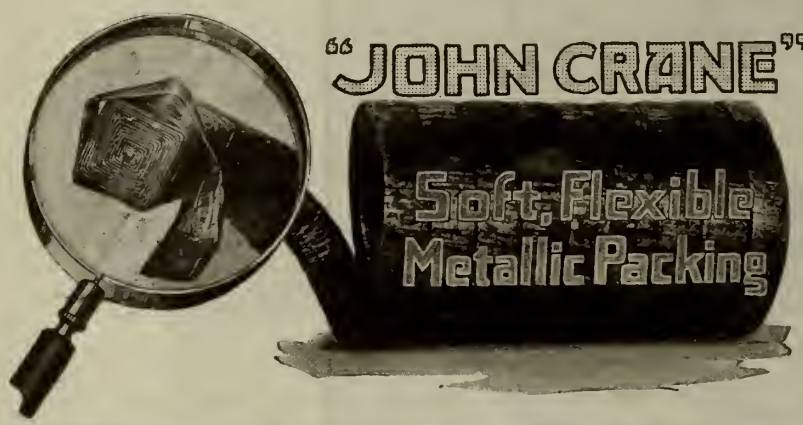
What is it that scores your rods and plungers? What touches them? Packing!
Did you ever stop to figure the cost of machining and replacing rods?
Did you ever realize that Fabric Packing was responsible?
Did you ever look for a different kind of packing which wouldn't cause such costly troubles? Think it over—

Why Use Trouble-Making Fabric Packing?

SCORED rods, "blow-outs," nights and Sundays spent repacking, all are the direct results ot using packing made of fabric, a friction creating material.

"John Crane" is made of babbitt. It is frictionless as your babbitt bearings. It is soft, flexible and compressible—made of thin foil ribbon, wound layer upon layer with lubricant in between. You can cut it with a knife.



Never hardens—never needs to be replaced—just add a ring as needed.

Use it for all services—steam, air, water, in fact everything. Send your order *now*. Get acquainted with "John Crane."

RECOMMEND IMPERIAL FUEL OIL

IMPERIAL Fuel Oil has proved itself most efficient for use under boilers for steam generation.

Great Munition Plants that used Imperial Fuel Oil during the war are already supplied with most of the necessary equipment. Many of these plants will find it a real economy to continue to use oil as fuel for firing their boilers.

Good heating engineers know that Imperial Fuel Oil is an ideal fuel. It is highly concentrated, always absolutely uniform, easily stored and easily handled.

Imperial Fuel Oil makes possible steady maximum heat under boilers, hence it increases—practically doubles—the steaming efficiency of any boiler under which it is properly used.

Judged by final results, Imperial Fuel Oil is one of the most economical fuels available to-day.

Imperial Fuel Oil is also excellent for heating Hotels, Apartment Houses, Public Buildings, Churches and Schools, where cleanliness and quick, reliable heat is of vital importance.

Those interested will obtain full details regarding Imperial Fuel Oil and the installation of any equipment necessary to burn it by writing or calling at Room 704, Imperial Oil Building, 56 Church St., Toronto, Ontario.

Elevates, Conveys and Automatically Dumps Coal, Ashes, etc.

Detail of Bucket

Upper Driving Corner

THE Peck Carrier represents positively the last word in coal and ash handling equipment. The coal is not scraped but **carried** in overlapping, pivoted buckets, from the cars to the bunkers over the boilers.

The elevating, conveying and automatic dumping of the coal is all accomplished by one piece of equipment. There are no transfers needed. The buckets are supported on rollers. Friction is largely eliminated and power required is reduced to a minimum. Operates silently and without vibration.

The Peck Carrier is also used for the handling of cement, crushed stone, gravel, etc. Catalog mailed on request.

CANADIAN LINK-BELT CO., LTD.
Wellington and Peter Sts., Toronto

LINK-BELT
PECK CARRIER SYSTEM

The Webster Vacuum System of Heating

can be likened unto the Matterhorn. It has an individuality all its own. From its pinnacle of fame it commands everything in sight.

The Webster System cannot be anything but a good system because of its simplicity and excellence of operation.

It is a **Vacuum System,** which means, crudely, that steam leaving the boiler is sucked through the radiation, no matter where placed, and made to perform its functions to the last ounce.

But the real beauty of the thing is this: Your heating, or a large part of it, can be taken care of by the use of **Exhaust Steam from your Boiler. Think of it,** steam that you would otherwise waste can be developed into heating units by the use of the **Webster Vacuum System of Heating.**

Dominion Friction Surface Belting

Conserves Power and Labor, Increases Production, and Cuts Manufacturing Costs

The lowest possible manufacturing cost is obtained only through highly efficient equipment that will conserve power and labor and "speed up" production.

Dominion Friction Surface Belting is the most economical and efficient transmission equipment obtainable.

Dominion Friction Surface Belting is more than waterproofed fabric—it conserves power by taking a "bull-dog" grip on the pulleys, that practically eliminates slipping and transmits the maximum force that can be transmitted by a belt.

The economy, uniformity and dependability built into each foot of Dominion Friction Surface Belting insure long and continuous service, which saves much time, energy, trouble and worry for employees, and prevents idle machines by removing the cause of transmission troubles.

Dominion Friction Surface Belting "speeds up" production by giving long and continuous service—by conserving power and labor and insuring satisfied operators.

Put a Belt as Good as this on *Your* Pay-roll

This Graton & Knight 40" 3-ply Heart Brand Belt is five years old. It is running every day on heavy duty for the Milford Light and Power Co., Milford, N.H. The cost of this belt in cash has been $1.81 a week, or .004 per delivered horse-power per week.

Put a belt as good as this on your pay-roll. Its low cost of upkeep is the result of Graton & Knight Standardization. That means the proper belt for any given requirement. It means the right quality of leather and the right kind of tanning for a given purpose. It means true economy—full delivery of power, without waste.

Leather is the ideal belting material. It has a characteristic pulley-gripping quality. It has pliability with light weight. It has the stretch and the come-back that gives and takes. It stands mauling by shifters and the gruelling strain of main drives. It is firm and strong. It is tough, but tractable. These are the characteristics that good belting must possess.

Every year nearly 300,000 hides are tanned in the G. & K. factory. That gives uniformity. The more stock handled, the more latitude there is for picking equal-quality material for a given specification. And G. & K. Tanning is of a fixed standard of quality for specific requirements. We make all kinds of leather belting, for every use—large and small.

Load carried and conditions of operation must figure largely in the length of service of any belt. Some drives limit belting to a few months or even a few weeks. Graton & Knight Standardized Series Belts are made to give the longest possible delivery of efficient power at the lowest possible cost. And they do it. It may be that belts all look alike to you—and it may be that you are spending more than is necessary for some belting requirements. We can and will help you find out.

Many of the best-belted plants ask us to specify the belting for every drive. Try the plan yourself. Then, when buying, call for "Graton & Knight——Brand or equal." This won't commit you to buying our belts. It will put your buying on the one basic consideration—the work to be done.

Wanted—

Engineers to Contribute to Power House

THIS is a practical paper for practical engineers. It is an educational medium and out to help its readers. It is a technical school and a social meeting place combined. It is first, last and all the time an engineer's paper.

If you should meet two or three or a dozen of your brother engineers you would swap ideas—you'd tell of some idea you had worked out in your plant. Others would describe some pet schemes they had devised. And so you would be mutually benefited.

Why not make Power House your monthly meeting place? Why not describe in this paper some kink or scheme you have worked out and found successful? We will pay you for it and you, in turn, will be multiplying the usefulness of your idea five thousand fold!

Never mind polishing up your letters—just give us the idea; that's the main thing. Never mind how crude your pencil sketch may be. We have draughtsmen who will finish up your drawings so they may be reproduced.

Try this idea a time or two and see how much satisfaction you'll get out of it. Start the ball a-rolling and thus help other engineers, yourself and your paper.

THE "NEW" MACLEAN'S

Starting with the January issue, MACLEAN'S MAGAZINE comes out in a new size—11 x 14¼—same size as *The Saturday Evening Post.* This change will enable us to give readers more entertaining articles and stories, and a very much enlarged "Review of Reviews" Section. You will find this January issue of MACLEAN'S more pleasing and instructive than the great majority of magazines you find displayed on news-stands—and

contents are carefully censored—no sex stories—you can take it into your home with the utmost confidence.

A word about the contents—

"Why Laurier Will Wait"

In discussing the policy of the Liberal leader during the coming session of Parliament, J. K. Munro predicts, in January MACLEAN'S, that Laurier will allow Union Government a free hand. In this policy of inactivity "he sees the way open to the accomplishment of all his purposes. If he is half the politician his friends believe he is, he will sit and smile and wait—yet a little longer."

All Canada is interested in what is going to happen in Ottawa. J. K. Munro, veteran press gallery man, is a shrewd observer, and his political articles in MACLEAN'S have stirred up more comment than anything else appearing in the press of the country. He knows politics from the inside. "Why Laurier Will Wait" is a forecast of the near future that bristles with interesting points. A few of the other "head-liners" in this issue:

Bolsheviks at Work in Canada

A sensational article on activities in subterranean circles. There are foreigners in Canada ready to wave the red flag.

Achievements of the Canadian Army

Since the Canadian Division was formed, they have not retired a foot nor lost a gun—a marvellous record. An inside story of how this great army was handled and controlled is told by H. F. Gadsby who spent a month at Headquarters during the last great offensive.

The Grave Dangers of Peace

An article by Agnes C. Laut on the insidious new propaganda being launched by the Germans to split the Allies.

Jock in a Juggernaut

The most interesting war article in a long while, because it is new—it deals with experiences in the tanks.

AND THESE AS WELL:

The Dance Halls of Dawson - By E. Ward Smith

My Hour - - - By Robert W. Service

The Strange Adventure of a Rialto Rainstorm - By Arthur Stringer

The Minx Goes to the Front - - - - By C. N. and A. M. Williamson

The Three Sapphires - - By W. A. Fraser

Mr. Craighouse, of New York, Satirist - - By Arthur Beverley Baxter

Buy Thrift Unions—

JEFFERSON UNIONS

THRIFT—our national watchword—must be practiced on every opportunity and from every angle. It is of utmost importance that waste of labor and materials be eliminated. JEFFERSON UNIONS are Thrift Unions because they conserve labor and materials. "Just-as-good" unions require almost as much material as "JEFFERSONS," shipping and installation costs are equal—but when the defective union breaks down, there is the added expense for repairs.

"SAFETY FIRST"—Insist on getting dependable unions. It's too late to investigate when superheated steam sizzles out of the "just-as-good" connection. The best sounding promise is valueless after the damage is done.

Your jobber has "JEFFERSONS" in stock that will meet practically every condition about the mine. Just look them over and you'll see why it's always safer to "look for the name on the nut." Write to-day for our Catalog. "UNIONS," which shows every JEFFERSON style and type.

Stop Those Packing Leaks

Vulcabeston Red Fibre Sheet Packing is positively unsurpassed in endurance and effectiveness. Whether used in saturated or superheated steam, compressed air, gas, acid, or ammonia systems—low pressure or high—it invariably makes a tight joint that remains perfect throughout all degrees of moisture and temperature. It is made by a special process from long fibre asbestos and is thoroughly heat resistent and impervious to moisture and chemical action. The result is a general utility packing that *works* right in *every* class of service.

VULCABESTON
RED FIBRE SHEET PACKING

is easy to cut and apply, resilient and pliable, yet unlike rubber, cannot squeeze out or stretch. Where other packings have failed to permanently seal a joint and where unusually difficult conditions exist you can confidently depend on it. Use Vulcabeston once and like hundreds of other men, you will never do without it. Send direct to us or have our nearest dealer supply you.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs*. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

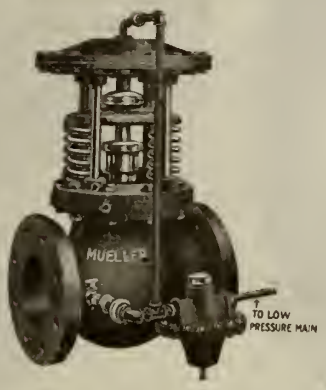
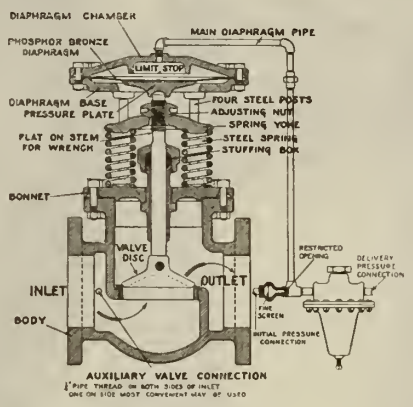
MUELLER Reducing and Regulating Valve

SINGLE SEAT; AUXILIARY OPERATED





E5030 for Water, Gas and Air
E5130 for Steam
(Flanged or Screwed)

Very Popular with Shipbuilders

USES

This valve is for use on exacting installations. It will make any desired reduction and will maintain a constant delivery pressure regardless of fluctuations of the initial pressure.

CONSTRUCTION OF STOCK REGULATORS

All valves have iron bodies, bronze stem and stuffing box, phosphor bronze diaphragms, seats of composition suitable for the required service; iron diaphragm chamber and steel springs. The main valve is controlled entirely by the small auxiliary valve. This auxiliary valve closes and opens the main valve by admitting initial pressure to, and releasing it from, the diaphragm chamber of the main valve according to the demand of the delivery side. Regulators of this description are suited for pressures up to 150 pounds, and will be furnished at above prices. When regulators are required for pressures in excess of 150 pounds we will furnish suitable material. Prices upon application.

STRAINER

In all cases it is advisable to use a strainer to prevent obstruction from grit, scale, cuttings, etc. Blow out pipes thoroughly before installing valve.

INFORMATION IN ORDERING

In ordering give highest and lowest initial pressure and required low or delivery pressure, approximate quantity or volume to be used per minute, size of high pressure pipe and low pressure pipe.

In ordering flanged end valves give diameter of flanges and bolt circles and the number and size of bolts.

INSTALLATION

Note.—Any proper working regulator acts as a check valve. Where the building up of the pressure is to be avoided use our diaphragm operated relief valve E5060.

We will not be responsible for improper selection of valves.
Consult us regarding the best type for your service.

During the period of the war, our every effort was centered on the one most important object,—VICTORY FOR AMERICA AND THE ALLIES—and we practically confined our entire output to war necessities.

Obviously, during this period, it was impossible for us to fully meet the requirements of the commercial trade and we were forced to ask that orders be confined to absolutely essential needs.

In graciously complying with our request, OUR PATRONS HELPED US TO HELP WIN THE WAR and we take this opportunity of sincerely thanking them for their co-operation.

Victory has left us free to readjust conditions within our plant and we will soon be in a position to fully meet the demands of the trade, when we hope to demonstrate by faithful and prompt service, our appreciation for the consideration shown us by our patrons during the war.

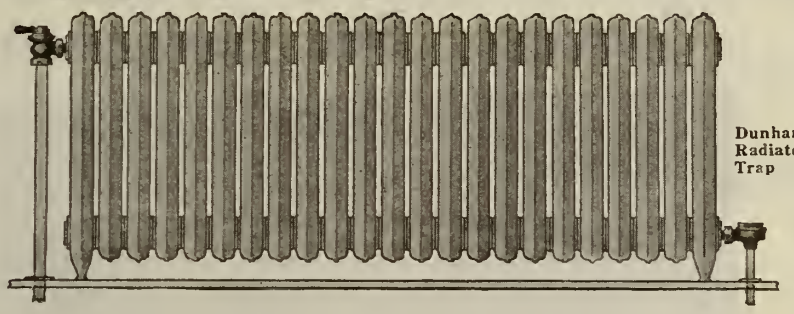
Heating Service that Boosts the Efficiency Curve

Noise in a steam heating system indicates inefficiency; so do leaky valves and partly-hot radiators. No matter how good the boiler and radiators may be, they cannot do good work unless the steam circulates properly through the entire system.

By eliminating heat-waste—whatever the cause—Dunham Heating Service contributes to the efficiency that must be obtained for profitable peace time production.

Thousands of industrial plants, office and government buildings have Dunham Heating Service, which is recommended by leading architects everywhere.

Dunham Packless Radiator Valve



The Dunham Radiator Trap automatically permits the discharge of air and water—keeps in the steam. The Dunham Radiator Valve is really packless—cannot leak.

Write for complete details of Dunham Heating Service which covers the planning and installation inspection of heating systems that give satisfaction.

VIGILANT

Can you keep your boiler water within a ¼" of middle gauge? That is what the Vigilant does regardless of the load or firing. The Vigilant Automatic Feed Water Regulator has many points of interest economically.

Our catalogue will interest you —write for it.

The Chaplin-Fulton Manufacturing Company

28 Penn Avenue - Pittsburg, Pa.

DAVIS

BACK PRESSURE VALVES

are designed to maintain a constant back pressure of steam for heating, drying, cooking or other purposes where light pressure is needed. On the exhaust line of a non-condensing engine, the Davis Back Pressure Valve fills the need. For use with condensing engines or turbines the Combination Back Pressure and Exhaust Relief Valve maintains the back pressure when running non-condensing and acts as an exhaust relief when operating condensing. Noiseless and absolutely reliable — cannot stick or bind.

These consistent steam savers are all illustrated and fully explained in the new Davis Engineering Booklet. For your free copy address the G. M. Davis Regulator Co., 434 Milwaukee Av., Chicago. Branches in principal cities.

STEAM SAVERS SINCE 1875

Conveyor Belt Service Almost Tripled

From 6 Months' Service to 16 Months' Plus

The famous Dome Mines in South Porcupine, Ontario, were not dissatisfied with their conveyor belt service. Their belts had been averaging six months' service, even on a difficult shuttle conveyor—a rigorous test.

However, in August, 1916, they were induced to try their first Goodyear Extra Duty Conveyor Belt on this shuttle conveyor, driven by a motor at either end. It distributes ore from a long conveyer to the stamp mill bins, handling 750 to 800 tons a day.

The belt we recommended was 80′ of 8″ x 5 ply Extra Duty with ⅛″ face.

When the plant closed sixteen months later that belt was still in use and good for months of additional service.

Almost three times longer service than other conveyor belts gave.

Three simple, but very important reasons explain the remarkable service given by Goodyear Extra Duty Conveyor Belts in Dome Mines as in every other plant where these belts are used.

1. Durability and resiliency of white face made as tough as a tire tread.
2. The complete adhesion of cotton and rubber making the belt a permanent unit.
3. A rubber cushion edge that protects conveyor against wear on the edges—wear that on ordinary belts frequently causes disintegration.

If your conveyor costs appear high—if you appreciate uninterrupted conveyor service in your plant, then write, wire or telephone for a Goodyear belting man to discuss your conveyor problems with you.

The Financial Post on Business Government

"LET us demand that the standard of efficiency in the Government be raised to the highest possible point by the calling in of more of the business executives of the country to take the place of the arm-chair politicians who win to position by the ability to win votes rather than to serve the interests of voters. Let these men assist in the negotiations for reconstruction business from Europe, the financing of such orders on a business basis, the establishment of proper trade relations with foreign markets, the readjustment of taxation and the tariff to a more intelligent basis in relation to individual industries, the efficient demobilization of the soldier and other problems of policy, but let every individual meet for himself those other problems which concern those whose welfare depends upon him and solve them to the best of his ability. Reconstruction begins at home. Let us have confidence in ourselves."

Beside the vigorous leading article from which the above is quoted,

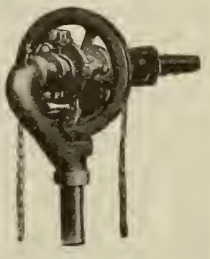
SAVE 4 to 8 PER CENT FUEL

COST MORE AND WORTH MORE

STANDARD OF THE WORLD

The Prophets May Be Right or May Be Wrong

A Message to the Canadian Power Users

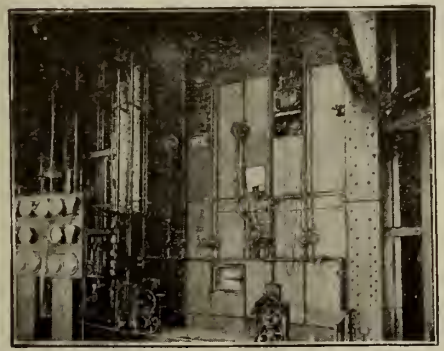


They Say That 1919 will be the biggest year in the history of Canadian Industry; that our factories will be taxed to the limit of their productive capacity in the effort to supply goods needed for deferred domestic demands, such as building construction, re-habilitation of railroads, ship-building, automobiles, replenishment of depleted stocks etc., in addition to an extremely heavy export demand from all over the world.

If They Are Right Your factory will undoubtedly be called upon to carry its share of the general burden. This burden will be a profitable one. You can make it more profitable by developing greater productive capacity from the equipment used. As the best illustration we know of, take your boilers. They are not operating to capacity if the heating surfaces are coated with soot and ash.

Diamond Soot Blowers installed in your boilers will, as compared to the best possible efforts of your fireman with the hand lance, effect the following economies.

1. FUEL: A saving of 4 to 8%
2. BOILER EFFICIENCY: An increase of 4 per cent.
3. LABOR: A saving of many hours per day.
4. LONGEVITY: An increase in the length of service of boiler tubes, through the prevention of corrosion.
5. STEAM: A saving of 25 to 75 per cent of steam used for cleaning.



Diamond Soot Blowers at Plant of Buffalo General Electric Co.

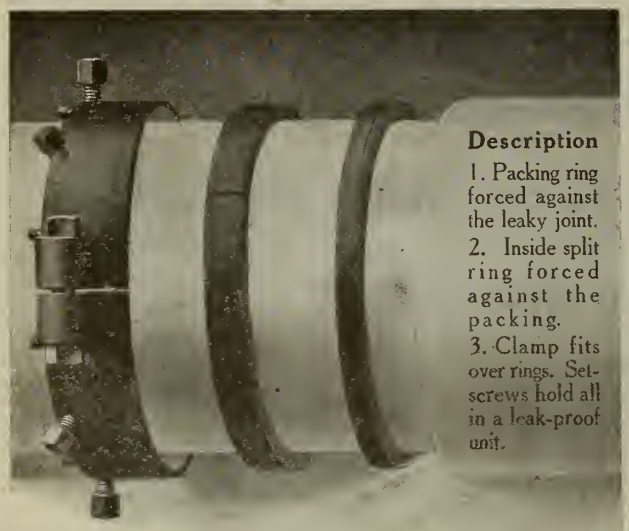
If the prophets are right DIAMOND SOOT BLOWERS will enable you to produce a greater volume of goods.

If They Are Wrong If business does not reach unprecendented new levels—if your plant is not called upon to produce to its fullest capacity—your only hope of material profits lies in reducing your production costs. DIAMOND SOOT BLOWERS will cut the cost of power and will earn you 100% to 250% annually upon your investment.

Hundreds of plants in the Canadian field are now equipped with DIAMOND SOOT BLOWERS. For full information write for Bulletin 119.

Diamond Specialty Company
Windsor **Ontario**

MADE OF CALORIZED STEEL



Description
1. Packing ring forced against the leaky joint.
2. Inside split ring forced against the packing.
3. Clamp fits over rings. Set-screws hold all in a leak-proof unit.

You Can Stop That Leak

—And stop it permanently—with a Simplex Pipe-Joint Clamp.

It does not make much difference how big the opening may be—provided, of course, it is not beyond repair. Nor does it matter a great deal what is in the pipe—water, steam, gas, air, oil, ammonia, brine, etc.—the leak will be stopped absolutely.

And as long as the Yarway is left in place that joint will remain tight.

The principle of the Yarway Pipe-Joint Clamp (formerly Simplex) is very simple. There are but three parts, as shown above—one packing and two iron rings.

Any workman can make the attachment without difficulty in a few minutes.

As an example of the way in which this serviceable clamp makes good, read what one user says:

> "The fact that from the date of its installation, we have not realized that there is a steam joint at the point where placed, is sufficient evidence that it fills the bill."

Try a Yarway for 30 days subject to return if not satisfactory in every way. Write to-day stating size of line.

No Mystery About BETSON'S

REG. U.S. TRADE MARK PAT. OFF.
PLASTIC FIRE BRICK

It is merely an exceptionally high-grade compound of the best fire clays, given a special mechanical preparation which eliminates expansion and contraction and thus renders it suitable for one-piece boiler-furnace linings. It comes in bulk in barrels in a plastic condition, ready for use, and is placed in chunks and pounded into place with a mallet and afterwards smoothed with a trowel. No special skill is required. Almost anybody can put it in place, the work is so perfectly easy and simple. There is no waiting for expert brick layers, or for shipments of special fire brick or blocks.

A sketch of your setting, like the one herewith, showing the dimensions and present thickness of fire brick, will enable us to estimate upon the quantity required. If you are not ready to replace an entire lining, order a barrel or two for repairs, which will demonstrate its superior durability and tightness. Then when you are ready to reline you will surely use Betson's.

40,000% PROFIT

Enormous Profits In Stopping Belt Slip

Ever hear of anybody making 40,000 per cent. profit on Wall Street? We haven't.

Well, this is the way you can do it: One man kept his belt in a slipless condition with Cling-Surface for over eight years at an average cost of 27 cents per year. Based on the formula published in our ad in Power House last month the annual saving was $108.

108÷0.27=400=40,000 per cent. profit.

Every user of Cling-Surface is making similar profits. It is impossible to do otherwise.

In order to save $108 anywhere else the average business man would perhaps spend $90 or $100. Why should belt users, then, hesitate to spend 27 cents to save $108?

But the "beauty of it" is—that isn't all. The profits are even greater. When a belt stops slipping it lasts longer. Belt wear is due entirely to friction—internal or external. So, although these additional profits depend entirely upon conditions, doesn't it seem possible that the final profits may be 50,000 per cent. or even more?

Cling-Surface keeps belts in NATURAL condition. It makes and keeps them pliable and "grippy" without making them the least bit sticky. It PENETRATES the belt, surrounds, lubricates, and thus protects every tiny fibre. Cling-Surface is the logical, proper treatment that every belt man should apply to stop slip, save belts, increase output, and save much money.

Write TO-DAY for a 50-lb. can. Use one month. If results aren't satisfactory return the remainder at our entire expense.

Cling-Surface Co.
1057 Niagara Street
Buffalo, New York

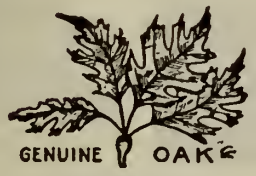
That Belt you're going to Buy—

HAS IT THE QUALITY THAT MAKES FOR LONG SERVICE?

IS IT BUILT TO HUG THE PULLEY TIGHTLY AND PREVENT POWER WASTE?

IS IT BUILT TO REDUCE STRETCH AND ATTENTION TO A MINIMUM?

To convince you that *D. K. McLaren's Belting* service answers this problem to the last letter we'll gladly put you in touch with many of the largest Canadian power plants.



REGISTERED TRADE-MARK

This trade-mark guarantee is on every piece of D. K. McLaren's Leather Belting. Look for it.

D. K. McLAREN'S

Genuine British Oak-Tanned

LEATHER BELTING

is made exclusively from close-trimmed butts of the finest selected hides, tanned by the old-fashioned but the proven most effective British Oak Tanning Process.

Try one belt—and you'll want to buy more.

Dominion Belting Company, Limited

Hamilton, Canada

Sole manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

BEST HE EVER USED

WORCESTER, MASS.
9 Concord Street.

June 26, 1918.

Gentlemen:—

Your metal was first introduced to me by a retired engineer some 17 years ago.

That day when I broke in on this job we lined both main bearings on this engine (Harris Corliss Compound) while we shut down on account of a two-day holiday. I remained on this job 3 years and 4 months, and I did not have any bother with those bearings after that. How long they lasted I do not know, but that was the best metal I ever did use and will always use and recommend it to all engineers who are not acquainted with its wonderful wearing qualities.

Very truly yours,
MATTHEW F. EARLY.

Production Cost and Profit Depend on Belting Efficiency

The "MORSE" Rocker Joint Silent Chain is the only 99% efficient transmission known.

The more severe the duty the more need of "MORSE" Drives. The Drive that will do the most work, the steadiest work, the best work. Producing more with less COST. The Perfect Drive. Flexible as a belt. Positive as gears. Oil Baths not required.

Continuity in operation, Cost of production, and Quality are the basis on which to select your drives.

Let us have your general layout and design drives to save space, light and power while increasing your production.

Our booklet is illustrated with cuts of engines and drives and covers the subject of the number of teeth and links, lubricating and covering, chain and sprocket materials, chain widths, chain contacts, chain adjustments, etc. It will be sent FREE.

NOTICE

TO

Stationary and Hoisting Engineers

Everyone operating a STATIONARY steam plant of 50 h.p. or over in the Province of Ontario must hold a Stationary Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Everyone operating a HOISTING steam plant working at a pressure of 20 pounds or over, irrespective of horse power, and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a Hoisting Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Application forms for obtaining STATIONARY or HOISTING Engineers' Certificates, may be had upon applying to the Chairman.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914 With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID.

ADVERTISING to be successful does not necessarily have to produce a basketful of inquiries every day.

The best advertising is the kind that leaves an indelible, ineffaceable impression of the goods advertised on the minds of the greatest possible number of probable buyers, present and future.

Concluding
A YEAR OF
ACHIEVEMENT
ECONOMY
renewable FUSES
have played a noteworthy part in North America's wonderful industrial progress of 1918 by effectively safeguarding millions of important electrical circuits against the fire and accident hazards of overloads and short circuits.
They have directly saved millions of dollars for their thousands of users and have conserved large quantities of needed metals and fibre because an inexpensive "Drop Out" Renewal Link restores a blown Economy Fuse to its original efficiency.
Through the reconstruction period Economy Fuses will continue as important factors of economy and conservation.

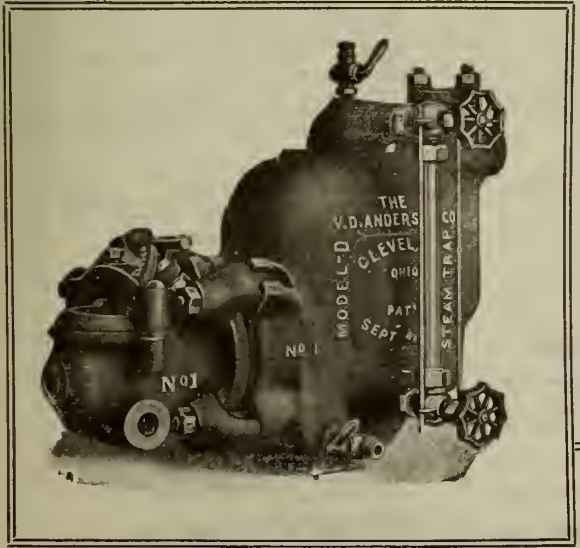
The Trap that Stays Tight

It means something to you in time, labor and expense to have a trap in your steam-room that will stay tight from the day you put it in. This dependability under high and low pressure is found in the

Anderson Model "D" Steam Trap



Features of this trap include simplicity of design, quick action and large capacity. It is operated by a counterbalanced LAKE SUPERIOR COPPER FLOAT. Has large air valve that will not wire draw and is always under deep water seal.

A self-contained strainer, an outside gauge glass, a self-contained by-pass and complete accessibility to all parts are other outstanding features of the Anderson Model "D" Steam Trap.

If you are troubled with condensation or any boiler room trouble, get in touch with us and secure our co-operation.

THE V. D. ANDERSON COMPANY

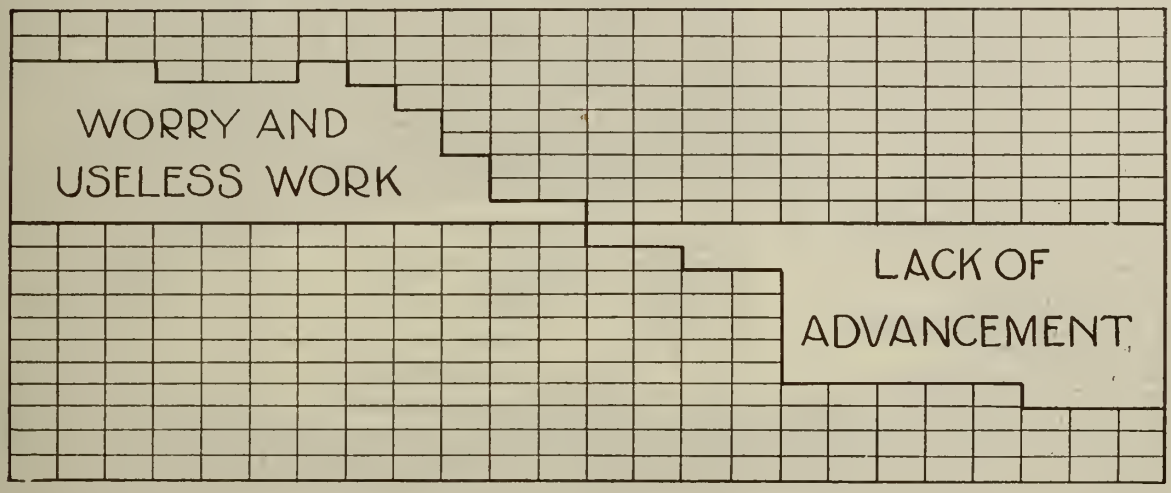
Let the C.A.S.E. Smooth Out Your Load Curve



Remove The Peaks of Worry And Unproductive Labor And Build Up The Valleys By Working For Your Advancement

A man who is thoroughly grounded in the practice of his profession, who is free from personal worry and trouble, overcomes the many difficulties besetting the path of the operating engineer with little labor and in a manner ensuring his advancement.

The successful man owes his success to a wise appreciation of the advantages and mutual help offered by association with those in the same field of endeavor. To join an association having for its objectives the welfare of the engineer in things mental and material, his advancement in knowledge and skill, his protection by provision for sickness and distress is to take advantage of an opportunity indispensable to all who hope to better themselves.

If you are interested in such an organization and live where less than fifteen engineers are located, send for a copy of our constitution and application blanks for admission to nearest branch lodge. If there are more than fifteen engineers in your community, get together and send for particulars regarding formation of a branch lodge.

J. H. HALE, General Secretary,

Canadian Association of Stationary Engineers

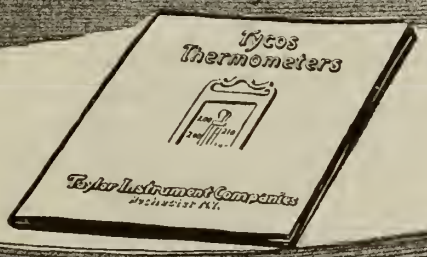
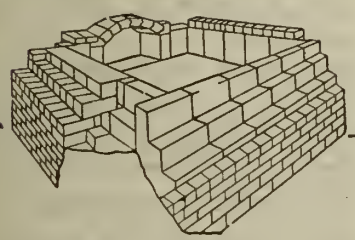
Tycos Catalogs

should be on the desk of every individual interested in the Indicating, Recording and Controlling of HEAT

Write for them specifying the type of Instrument you are interested in



Taylor Instrument Companies
ROCHESTER N.Y.



Gates Boiler Furnace

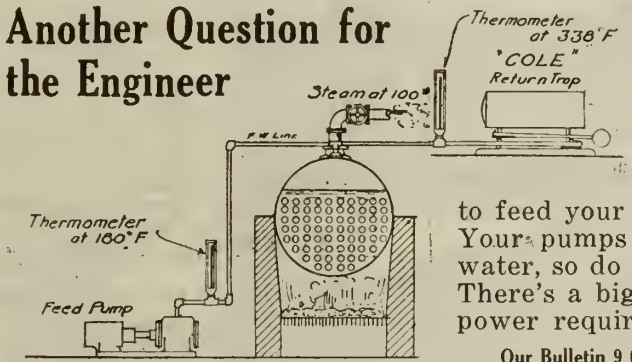
Patented 1916

Will last three times as long as ordinary good grade Fire Brick. These blocks are inter-locking, and made so that any handy man or fireman can renew them without disturbing any of the other brick work.

WRITE FOR PARTICULARS.

John W. Gates 2 St. James St. MONTREAL, QUE.

Another Question for the Engineer



With the alternative feed arrangement shown here, "How much of your Boiler-power is required to feed your Boilers?" Your pumps handle the feed-water, so do your return traps. There's a big difference in the power required. How much?

Our Bulletin 9 tells you. Write for it.

GEO. W. COLE, Limited, 2002 Dundas Street W., TORONTO

Save 8 to 20% of Your Coal

Coal is still scarce and high in price. A saving of from 8 to 20% must interest you. This is made possible with **Morehead Back-to-Boiler** system installed in your steam plant. It keeps condensation out of your steam lines by returning it continuously to the boilers HOT. Some concerns find that it makes an actual saving of 8%—others 15%—others 20%. In addition you get the greater efficiency of your steam heated machinery. The **Morehead System** is automatic and sure and simple in its operation.

Do you want to economize? Then here is the best way.

Canadian Morehead Manufacturing Co., Woodstock, Ont.

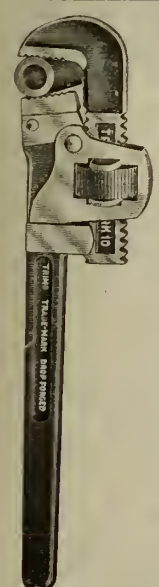
The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH



Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable ateel frames, in leading aizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulneaa of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inaerted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

INGLIS Engines and Boilers

In Canada's Greatest Industrial Plants

The larger the plant, the easier the sale—or so we have found it. For in the personnel of almost all great plants there is at least one mechanical expert who invariably holds out for the highest type of power equipment. In the judgment of such men certain features exclusively possessed by Inglis Engines and Boilers are vastly more important than price or favor.

Without charge, without placing you under any obligation whatever, Inglis Experts will answer your questions, consider your special requirements, and recommend the equipment best suited to your needs.

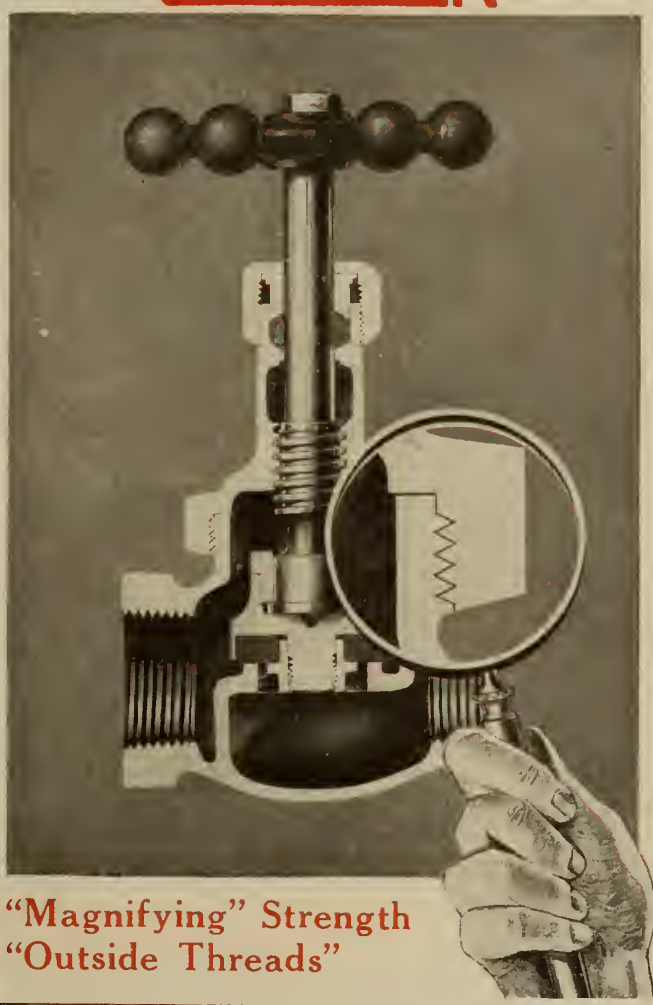
COMPODISK



"Magnifying" Strength
"Outside Threads"

PENBERTHY

PENBERTHY

All Penberthy Valves

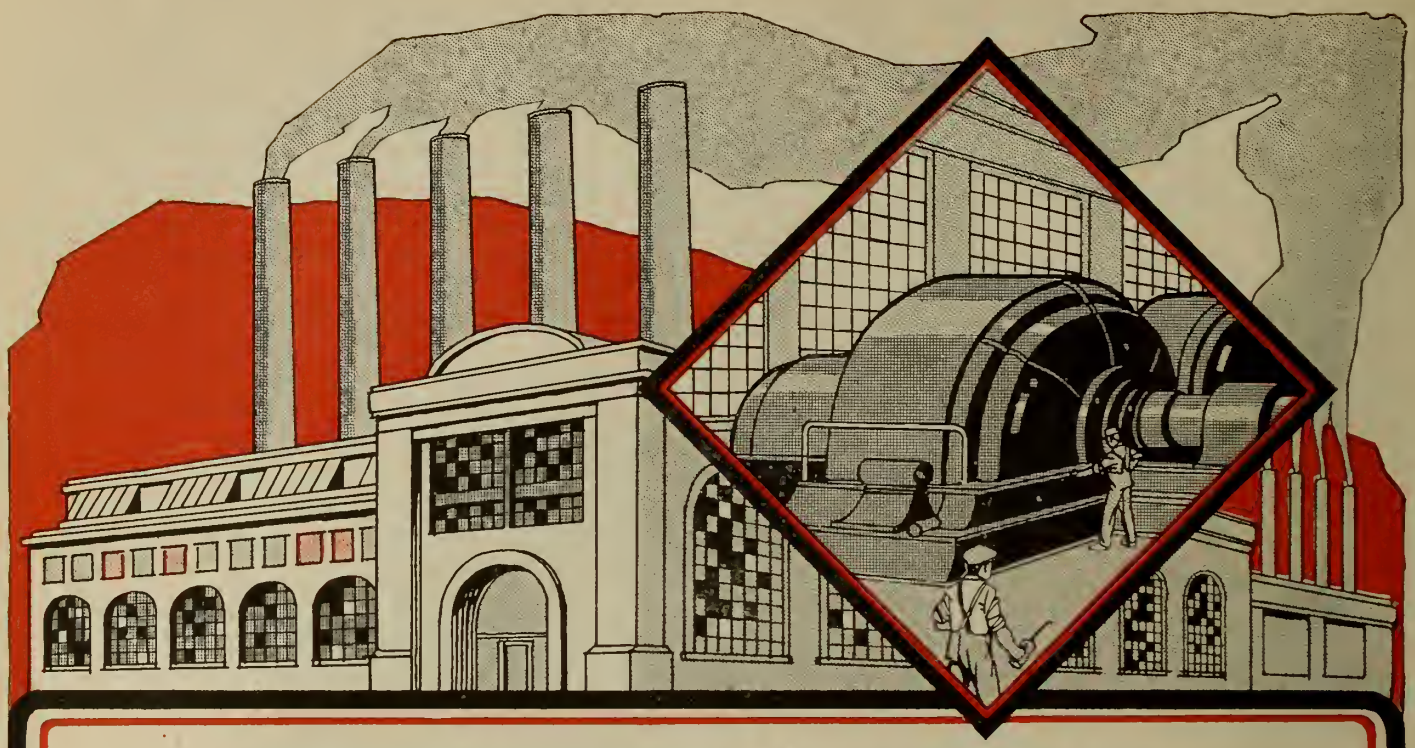
are designed with outside threads on the bonnet end of valve body. When tightening bonnet down to place this construction prevents spreading or enlarging bonnet end of body, causing a loose fitting and unsafe valve. The threads, being on the outside, are immune from the corrosive action of steam and water, thus preventing freezing of bonnet and body together and eliminating all strains.

It makes an extraordinarily strong valve at the vital point where others are weak.

LET IT PROTECT YOU.

MANUFACTURED BY

PENBERTHY INJECTOR COMPANY, LIMITED, WINDSOR, ONTARIO



MEET NATIONAL DEMAND WITH MAXIMUM OUTPUT

TEMPORARY shut-downs of engines or dynamos prematurely worn out must not be allowed to hamper the Dominion's effort to set new records in speed and volume of output.

Our line of scientifically-correct lubricants meets the needs of every type of power unit and the whole range of service conditions. It includes the following well and favorably known brands:

Imperial Lubricants

For Manufacturing, Mining and Milling

CYLINDER OILS

Imperial Capitol Cylinder Oil
Imperial Beaver Cylinder Oil
Imperial Cylinder Oil
Imperial Shield Cylinder Oil
Imperial Ebony Cylinder Oil
Imperial Acme Cylinder Oil
Imperial Disc Cylinder Oil
Imperial Dominion Cylinder Oil

ENGINE OILS

Imperial Atlantic Red Engine Oil
Imperial Bayonne Engine Oil
Imperial Standard Gas Engine Oil
Imperial Kearsarge Engine Oil
Imperial Renown Engine and Dynamo Oil
Imperial Solar Red Engine Oil
Imperial Junior Red Engine Oil
Imperial Eldorado Engine Oil

Smooth-running machinery is long-lived. Correct lubrication insures small repair bills, reduced production costs, maximum outputs — bigger profits.

We have a corps of experienced and competent lubrication engineers whose advice and counsel is at your service free of any charge or obligation.

Address our Home Office, 56 Church Street, Toronto, or any of our branches.

BRANCHES IN ALL CITIES

75 Years of Progress

1844 --- 1919

THREE-quarters of a century ago the name WATEROUS first came upon the industrial horizon of Canada.

Few thought then that the small concern, employing only a few men, would, in time, develop into what is now known as the Waterous Engine Works Co., Limited, covering acres of ground and employing hundreds of men.

During that time Waterous has continued to steadily increase until we are to-day one of the foremost manufacturing concerns on the continent.

But do you realize what these 75 years of business experience mean to the operators of Power Plants?

It means that when you install a Waterous product you have a machine that is built upon all the experience that the past can contribute to the needs of the present.

It means that our Engineers have had ample opportunity of studying the machines under actual working conditions and of giving careful consideration to all suggestions given by practical power house men.

It means that every time WATEROUS is put on an article it increases WATEROUS responsibility, for it represents our recognition of the fact that this past record of three-quarters of a century must be maintained.

For these reasons, when you buy WATEROUS products you get more than a mere machine—you get a machine that has dependability, efficiency and service built in.

Our Products Must Satisfy Us First

Waterous

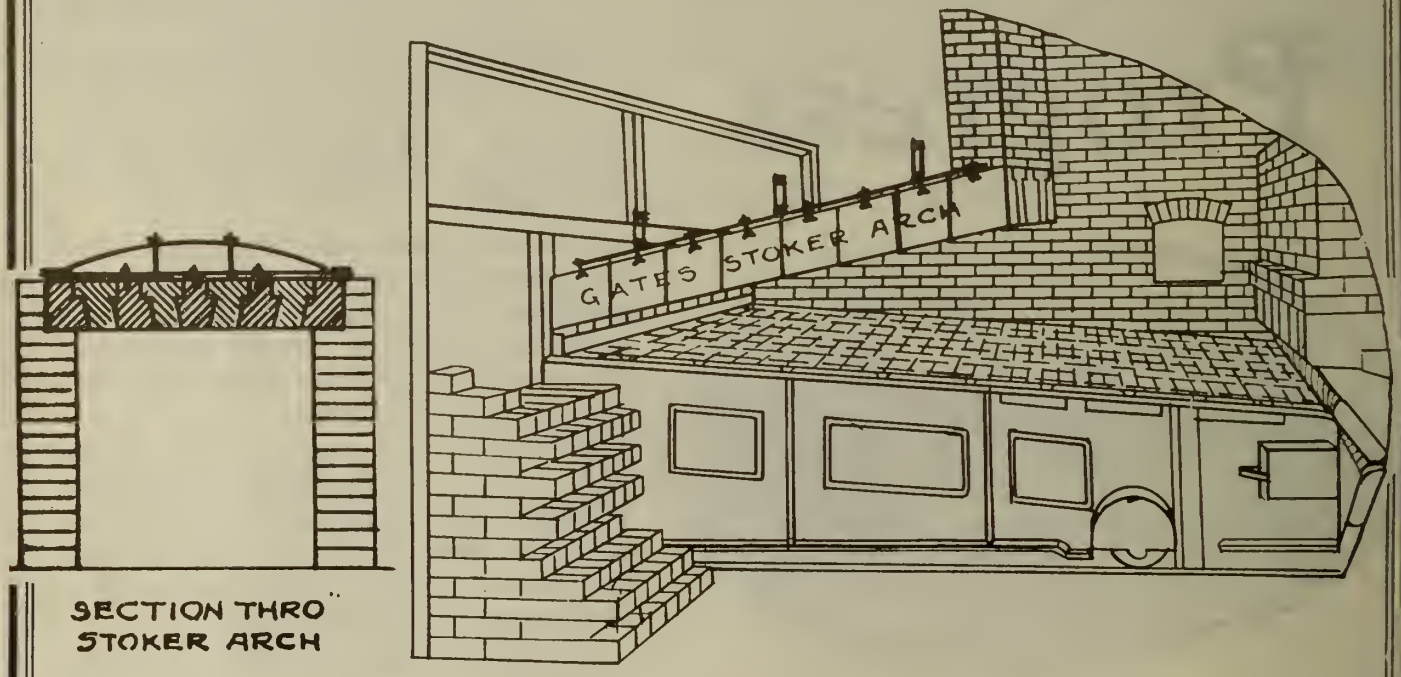
SPECIALIZING IN ALL KINDS OF

POWER PLANT BRICK WORK

Cut the cost of upkeep in your plant by using

Gates Patent Arches and Fire Box Linings



SECTION THRO" STOKER ARCH

GATES STOKER ARCH

¶ An arch that can be used on all kinds of stoker, dutch oven and reverberatory furnace.

¶ Being air tight it promotes better combustion.

¶ As the best of material is used and properly burnt it stands contraction and expansion and gives a longer life to setting.

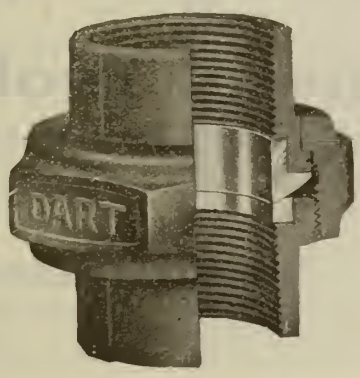
¶ One of the special features is when any part becomes fused it can be replaced by any handy man without taking down the whole arch.

¶ This means cutting your upkeep in boiler room 50%.

¶ If your setting is not standard we will design a block to suit your requirements.

CALL ON OUR ENGINEERS AT ANY TIME FOR INFORMATION YOU MAY REQUIRE. THEIR SERVICES ARE OFFERED TO YOU WITHOUT OBLIGATION.

DART Unions



Bronze—a metal that will not deteriorate —forms the face and seat

Extra Heavy Iron Parts give strength that prevents stretching or pulling apart

The Dart Union Stays Tight—*Permanently*

DART

Trade Mark

Dart Union construction makes for easy connection regardless of alignment of your pipe lines. The Face and Seat are Ball-shaped.

A trial will convince you that this is the safe, sure coupling that makes every job permanently right.

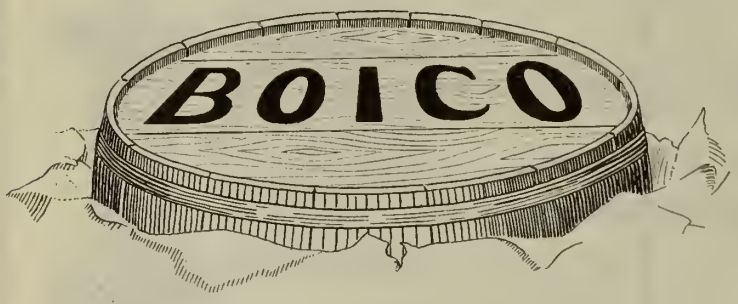
The Safe and Certain Boiler Cleanser



Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to instal.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**

BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

Uninterrupted Service

is absolutely assured with COPPUS Centrifugal Turbo Boiler Feed Pumps—a service that safeguards the boilers from shutdowns—the plant from lost production and lost products—and the engineer from care, trouble, and expensive repairs.

With this basic principal of uninterrupted service is combined a simple construction guaranteeing unusual durability, steady, even flow of water under constant control, and low steam consumption.

The many economies this pump will effect places small power plants on a par with respect to their boiler feed service with the largest plant in which specially built turbine driven boiler feed systems are installed.

The Type CCC pump requires practically no attention, and relieves the fireroom force of time-consuming duties. *Ready to ship.*

You will want to learn the details of this new pump and what it can mean to you in direct savings. Our engineering department is at your service.

Frick Company
WAYNESBORO, PA. U.S.A.
ICE MACHINERY SUPERIOR SINCE 1882
BRANCHES IN ALL PRINCIPAL CITIES

There is a FRICK Machine for every refrigerating purpose—all types: Vertical Horizontal—Absorption.

In the Home of "Sunshine"

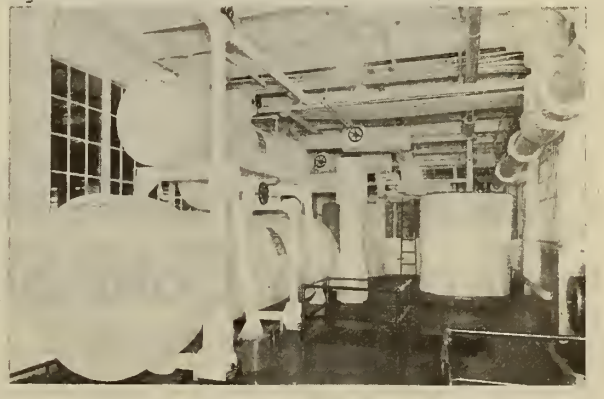
Down on Long Island, New York, the Loose-Wiles Biscuit Co., makers of "Sunshine" biscuits and other good things, have a big modern plant. Because it is modern in every respect, it goes almost without saying that the brine and ammonia lines, coolers, tanks, etc., are insulated with

Nonpareil Cork Covering

For Cold Pipes and Tanks

And so it is all over the country. Almost every up-to-date plant, large or small, has its cold pipes and tanks protected against loss of refrigeration with Nonpareil Cork Covering. They find, just as you will find, that money spent for Nonpareil Cork is money well invested. Dividends are paid every day the refrigerating machine runs.

Unless all of your cold pipes and tanks are insulated properly, you are wasting refrigeration and fuel needlessly. How to reduce this loss to a minimum is told in the 64-page, illustrated book, "Nonpareil Cork Covering for Cold Pipes." A free copy and a sample of the covering are yours for the asking.



Armstrong Cork & Insulation Company
504 McGill Building, Montreal, Que., Can.

Also manufacturers of Nonpareil Corkboard for cold rooms; and Nonpareil High Pressure Covering for steam lines.

A FAIR BARGAIN

It is unjust to charge too much for Refrigerating Machinery and poor business policy to charge too little. There is a point between where the buyer and seller must meet to conclude a fair bargain.

No transaction is ever entirely satisfactory that is not mutually beneficial. Goodwill never becomes an asset of any Manufacturer who charges too much for his product, and no Manufacturer can be successful who sells at less than a fair profit. Either the customer suffers or the firm sooner or later goes out of business. When you buy on the basis of price alone you generally pay for it and then some. Quality is remembered long after the price is forgotten.

If you are interested in Mechanical Refrigeration, we can furnish a plant to meet your local conditions at a fair price, all things considered.

The Quality and Service Guarantees back of all York Products should lead you to give us a chance at your business. Our interest in every plant after it is erected is a further protection to you and an assurance of our good intentions.

An inquiry from you will have our careful attention.

Overalls on Salesmen!

IN a purchasing agent's office in the morning; in the afternoon, in overalls, packing a pump in the engine room, building a baffle-wall or measuring power piping to be insulated; or a-top of a building inspecting or superintending a roofing job—this is not your idea, perhaps, of a salesman's routine day.

But Johns-Manville salesmen have never been of the kid-glove variety. They are first of all sales-engineers, and it is a source of just and lasting pride to us that the emergencies of war-time found them ready.

How to save heat and fuel, how to guard against fire—these are the lessons they have carried into countless plants the country over. It is not too much to say that by their man-to-man methods of preaching Asbestos and Conservation, our salesmen have rendered here at home a distinct service to the nation, have made a notable contribution to the efficiency of our war-machine, have helped the country in no small way to weather a national fuel crisis.

So we are proud that our men, appearing to advantage whether in business garb or overalls, have so completely justified the basic Johns-Manville policy. This policy is Service—the basis on which our goods are sold, the basis on which the properties of Asbestos are exploited, the very platform of our business. And as a personification of this policy, we can conceive of nothing more creditable to Johns-Manville than our salesmen in overalls, "helping out."

Canada Controls Nickel Output of the World

Plant of the International Nickel Co. of Canada, Ltd., at Port Colborne, Has Features of Interest to the Power Plant Engineer —This Refinery Assures Canadian Control of Nickel

By W. F. SUTHERLAND

View of refinery, showing main smelter building, machine shop, part of power house and nickel refinery.

FROM the earliest times, when man first emerged from the stone age, down to the present, iron and copper have been essential to his well-being and progress. Other metals, amongst them tin, lead, and zinc, have also been of much value to him throughout the ages, but it is only within the last century that nickel has assumed the importance its properties entitle it to. By itself, its brightness, non-corrosive properties and hardness render it one of the most useful of metals, and alloyed with iron, it was almost indispensable during the war.

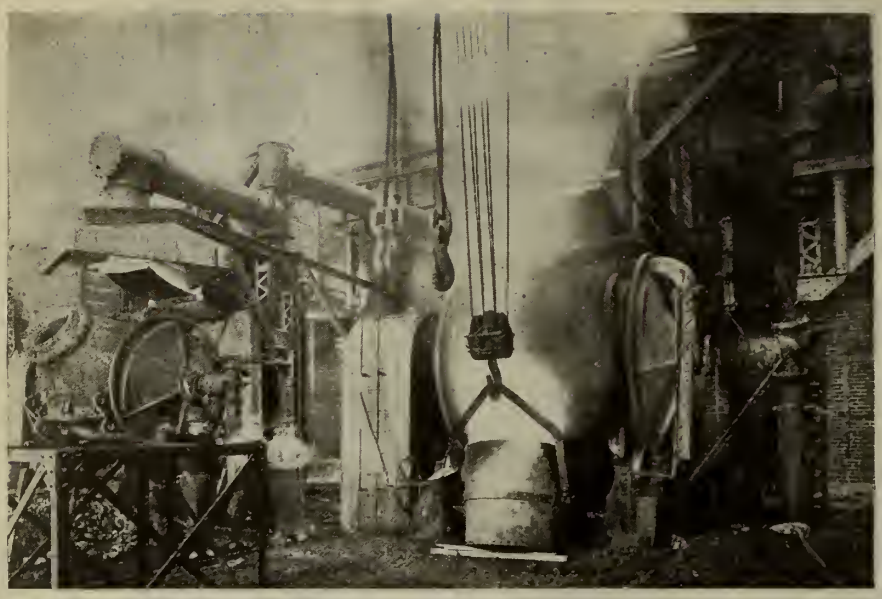
The importance of nickel in the recent war lends particular interest to the refinery of the International Nickel Co. of Canada at Port Colborne, the first refinery to be built on Canadian soil, and its successful establishment marks a new epoch in the industrial development of the Dominion. It has long been recognized that it would be of great advantage to the country and to the Empire at large to have Ontario's nickel industry self-contained within the borders of our own province, and an agitation has been carried on for many years with this object in view. Economic conditions have, however, in the past prevented the attainment of this very desirable object, the long freight haul and tariff on the necessary fluxes and other materials needed in refining have made it out of the question to refine at the mines. War conditions rendered it imperative that Canadian nickel be refined in Canada, and, after considerable study, Port Colborne was selected as a site where freight and other expenses could be reduced to a minimum, the longer haul on the materials imported being, in some measure, counterbalanced by the shorter haul from the smelter on the copper-nickel matte. Full advantage is also obtained from the lower cost of water haulage.

Together with the establishment of the refinery at Port Colborne, the Canadian Copper Company underwent a change in its organization, becoming entirely a subsidiary of the International Nickel Company of Canada then formed. It may be emphasized that this company is not an American organization and that its policy is to employ Canadian engineering talent and labor as far as possible, a feature contemplated for a good many years, ever since the desirability of establishing the refinery in Canada was considered by the personnel of the company.

Nickel as a Mineral

The geology of nickel and the location of the various deposits throughout the world are of considerable interest, and a knowledge of the mining and smelting of the ores is of value and may well precede the description of the refinery proper.

Contrary to popular belief, nickel-bearing ores occur in widely separated countries, Canada and New Caledonia having by far the largest and best deposits. The United States has some workable deposits which were worked for many years until competition from



POURING BLISTER COPPER FROM A CONVERTER INTO THE CASTING LADLE AFTER SEPARATION FROM THE NICKEL.

New Caledonia rendered it unprofitable. These deposits are located in widely separate parts of the country, and some is still being obtained from the blister copper refined at Perth Amboy, near New York.

Nickel Ores of New Caledonia

Next to the Sudbury region the French colony of New Caledonia, 900 miles east of Australia, is the most important source of nickel in the world, the deposits having been first discovered in 1865 by Garnier. Deposits of nickel, cobalt, and chromium are found in large beds on gentle slopes or basins on the flanks of the mountains; the nickel occurring as a hydrated silicate in which the nickel has replaced magnesia to a greater or less extent. The richest silicates, which are green and soft, may contain up to 48.6 per cent. of nickel oxide, but their composition varies greatly.

It is interesting to note that the New Caledonia ores practically never contain sulphur, being silicates accumulated in beds through the weathering of the original rocks, while the nickel deposits at Sudbury are in the form of sulphides associated with those of iron and copper.

The Sudbury Region

Sixty years ago, Northern Ontario, then a part of Upper Canada, was a wilderness, known only to a few Indians, who made a living as best they might by hunting, fishing, and trapping. The timber resources of the country were untouched, the vast mineral resources were unknown, and the fertile farm lands of the clay belt were thought non-existent.

The first intimation that valuable ore deposits might be found in the regions at the head of Lake Huron was made in 1848, in a report by Sir William Logan, then provincial geologist. He mentioned the fact that in one instance copper pyrites was accompanied by compounds of iron and nickel, with a trace of cobalt and stated that it would appear singular if a region extending over a space of between one and two thousand square miles, and giving marked indications of mineralization, did not, in the course of time, yield many valuable results.

From that time onward, various discoveries of copper and nickel-bearing ores were reported by various geologists and surveyors, who traversed the country, nickel being found at several places somewhat remote from what is now known as the Sudbury region. Nickel was first reported from this region by Murray in 1856. The well-known land surveyor Salter first reported indications of iron near the present Creighton mine, the greatest nickel mine in the world, his compass needle being very materially deflected by the iron with which the nickel is associated in the ore, and at his suggestion Murray investigated the deposit, finding copper and nickel.

As is often the case, the opening up of a country by improved transportation leads to its rapid development, and the utilization of its natural resources. The running of the Canadian Pacific in 1883 through the Sudbury district in this particular instance effected the discovery of important nickel deposits, as in the making of a cutting the excavation was carried through the ore body of what was afterwards known as the Murray line.

This exposure on the C. P. R. right of way gave the public some inkling as to the value of the minerals to be found and the country was quickly prospected, most of the important deposits of nickel and copper ores being found in a short time.

Geology of the Sudbury District

The nickel region has sharply-defined boundaries of a geological nature, since all the ore deposits are connected with a great sheet of eruptive rock, roughly boat shaped. Only the upturned edges of the sheet are exposed, since it is basin shaped and has its interior filled with sedimentary rocks. The basin is thirty-six miles long and about sixteen miles wide, and the known ore deposits are all either along the edge of the sheet, or less than four miles away from it on projections or offsets.

The Sudbury ores contain essentially only four ingredients, a magnetic sulphide of iron, which is practically free from nickel and copper, a sulphide of nickel and iron, a sulphide containing equal parts of iron and copper, and a variable amount of rock matter of several kinds. Some of the ores are low in copper and high in iron, and if these could be selected so as to contain only a minimum amount of copper, the large amount of iron present in the ore could be used directly in the production of nickel steel and much expense avoided. Recent researches have demonstrated that under certain conditions copper is not detrimental to steel, and it is possible that some method may be developed which will render possible the saving of the iron content in the form of a steel containing both nickel and copper.

The Canadian Copper Co.

The history of mining and smelting in the Sudbury region is so closely bound up with the Canadian Copper Co., now absorbed by the International Nickel Co. of Canada. that a good idea of the processes connected with the smelting of the ores may be gained by following the various operations as they are conducted at this company's smelter at Copper Cliff.

COPPER CONVERTERS IN REFINERY BUILDING

COTTRELL PRECIPITATION PLANT SEVEN 25 KW., C.G.E. MOTOR GENERATOR SETS SUPPLY ALTERNATING CURRENT TO THE STEP-UP TRANSFORMERS.

The valuable constituents of the ores are nickel and copper, and these two metals must first be separated from the useless materials and then from one another. The first step is the elimination of much of the sulphur found in combination with the nickel copper and iron of the ore, and in the past this has been largely accomplished by heap roasting, although it is anticipated that this process, destructive to vegetation and wasteful of sulphur, will soon become a thing of the past. For heap roasting, a flat, well-drained surface is prepared, and a layer of cordwood or dead pine is laid down to a depth of a foot or eighteen inches. On this bed coarse ores are placed, followed by medium ores, and finally by fines. The heap, when completed, contains up to 2,000 or 3,000 tons. and has a trim, rectangular shape. with flat top and sloping sides. The wood is set fire to and burns out, by which time the sulphur is ignited and burns without further assistance. Larger heaps require three or four months to burn, and at the end of this time all but about 10 per cent. of the sulphur has burned off and the iron is more or less completely oxidized.

After roasting, the ore is smelted in water-jacketed furnaces to standard matte. These copper blast furnaces are rectangular in shape and can handle about 500 tons of ore per day. The ore from the several mines owned by the company, owing to the large proportion of iron and admixture of rock with the sulphides, can be blended to form almost self-fluxing mixtures, but quartz is added as required to produce a further oxidization. The smelting results in two products, matte and slag. The matte contains practically all the nickel and copper. with much of the iron. The matte from the blast furnace is next poured into basic converters, where the remaining iron is oxidized in much the same manner as is the carbon in the familiar Bessemer converter of the steel mill. The iron passes out in the slag resulting from the operation, and a standard matte ready for refining results. This matte contains very nearly all the nickel and copper, very little of the iron, and a high percentage of sulphur. The matte is sent to the refinery at Port Colborne, where the copper and nickel are separated and refined.

The Port Colborne Refinery

On approaching the refinery one is favorably impressed with the excellent architectural features of the administrative and other buildings forming a group at the entrance.

The comfort and health of the large staff have been given considerable care, and the result is shown in the staff house provided for employees, and in the club house for the accommodation of the unmarried department and executive heads. This latter building contains recreative features such as bowling alley and billiard rooms. in addition to the living accommodations provided.

Laboratory

The laboratory is housed in a separate two-storey and basement building, and besides the offices necessary, contains the main laboratory and balance rooms. The laboratory has been fitted throughout with alberine or soapstone tables and a central fume hood with ten compartments has been arranged around a central stack. Each compartment is also constructed of alberine and has wire-inserted plate glass sliding doors with marble trim. The balance room is equipped with the usual precision and assay balances carried on an alberine slab free standing from the building, and supported on brick piers carried to bed rock.

Transportation Facilities

Railway sidings from the Grand Trunk enter the company's property from the north. These sidings serve every portion of the plant, and all handling of materials by hand being eliminated.

The furnace building, known as the No. 1 building, is 746 ft. in length by 125 ft. in width, and at present houses three blast furnaces and three converters. The matte received from the smelter at Copper Cliff undergoes its initial treatment here, and the method of handling the raw materials is of interest. The matte, coke and fluxes are brought in on an elevated trestle of reinforced concrete, and which displays excellent design and workmanship. From the cars the materials are dumped into elevated storage bins, from which it goes to the feeding floor and thence to the furnaces. The standard matte, 55 per cent. nickel and 24 per cent. copper, is smelted with saltcake, the nickel separated and the copper bessemerized in the converters. These converters are of Allis-Chalmers made, and are of 84 in. by 126 in. size. Electric tilting gear controls their movement. Besides these converters this company supplied two sets of crushing rolls and a sample grinder.

Removal of Fumes and Gases

In the various operations conducted in the No. 1 building much sulphur is given off in the form of sulphur dioxide gas, and to remove this and disperse it in such a manner as to prevent damage to vegetation has been a problem of some magnitude. Each converter has a stationary hood and also a movable one for use when pouring, through which all of the deleterious gases are removed and conducted to the stack. For the removal of dust and a valuable metallic content, the gases, before entering the stack, are subject to the familiar Cottrell precipitation process.

The Cottrell Precipitation Process

For many years there was no known process by means of which dust and other objectionable matter in flue gases and in the gaseous products of metallurgical operations could be completely eliminated. The Cottrell precipitation process, a somewhat recent development, has been applied to these uses with such success, however, that it has been well established as a standard means of removing fine particles of material such as dust, fumes, acid, mists, etc., from the gases, resulting from the smelting and refining of copper, lead, zinc, and other metals.

The installation of this system in the refinery at Port Colborne is one of the largest and most successful in North America, and is admirably planned for the work it has to do in the elimination of many of the noxious elements of the gases and in the recovery of valuable metals.

A brief description of the fundamental principles underlying the electrical precipitation process will be of much assistance in understanding the operation

B. & W. BOILERS SUSPENDED BUNKER, AND CHAIN GRATE STOKER.

of the plant. A body highly charged with electricity, if of small enough diameter, or with sharp points, discharges electricity silently through the surrounding air. The corona discharge surrounding high tension lines under certain conditions, and visible as a pale light, is an analogous condition. Some of the electrical energy thus discharged is imparted to any particles of matter in the immediate vicinity, and they in turn are transformed into charged bodies (positive or negative as the case may be). As bodies charged with electricity of the same sign repel each other, all such particles will, if free to move, be violently repelled from the fixed electrode or charged body, and will be attracted to a body of opposite polarity.

The essential elements in a precipitation plant then are a source of high potential direct current and the two electrodes of opposite polarity. One set known as the discharge electrodes, are of such form as will facilitate an electric discharge from their surface. This is accomplished by making them in the form of a wire or light chain or a strip of metal having relatively sharp edges. The other set of electrodes known as the collecting electrodes, are of such shape as to prevent as far as possible any discharge from their surfaces. in this case, in the form of a pipe with a smooth bore.

These electrodes are so arranged in the precipitator that the different types oppose each other, and between them a silent or glow discharge is maintained by supplying to the discharge, electrode energy of a uni-directional character. The collecting electrodes are grounded for safety, the ground being used as the return circuit.

In this refinery the fumes from the copper converters are collected by hoods and carried away in two collecting flues, which unite at the base of the stack. These flues are of concrete and steel construction and are lined with brick. The gases on the way to the stack pass through the precipitating tubes which are arranged in two separate groups, one serving each flue, and all particles of suspended matter are driven to the enclosing walls and drop into suspended bins below, from which they are removed from time to time by means of the company's railroad.

Energy is supplied by means of seven 25 kw. motor generator sets of General Electric make. These motor generator sets take current from the d.c. busses and transform it into lower-tension alternating current at sixty cycles. A step-up transformer for each set serves to step the voltage up to 100,000 volts, at which potential the current is commutated and led to the precipitating tubes. The commutator is a bakelite disc about thirty inches in diameter and is keyed to the end of the motor-generator shaft, thus keeping it in exact synchronism with the alternator frequency; two metallic sectors are attached to the disc and the current is transformed into a uni-directional current by means of fixed sparking contacts, no mechanical connection being necessary.

From the precipitator the flue gases pass into the stack, which is 350 feet high and 12 feet internal diameter at the top. This stack, together with all others at the plant, is built of reinforced concrete and was erected by the General Concrete Construction Co.

Air Supply

The converters and blast furnaces require a large volume of air, and for this purpose three high-pressure turbo-blowers are installed in a separate building. These blowers are made by the Ridgway Dynamo and Engine Co., and

INTERIOR VIEW OF POWER HOUSE, SHOWING WEBSTER-LEA HEATER METER, INGERSOLL-RAND COMPRESSOR, PUMPS FOR PLANT WATER SUPPLY AND TURBO-GENERATOR

EXTERIOR OF POWER HOUSE.

have each a capacity of 7,500 cubic feet of free air per minute, at 30 oz. pressure. The blowers are individually driven by high speed direct-current motors at 3,600 revs. per minute.

Further refining of the nickel is done in the No. 2 building, and one of the most interesting features of this portion of the plant is the comprehensive arrangement of the mono-rail system. The bottom chords of the roof trusses have been designed to take care of the additional load, resulting from the mono-rail system and Shepard crane and hoist mono-rail trolleys serve every portion of the plant. Safety features, suspended walks and runways are provided, and it is impossible for any car to run off an open switch or otherwise do damage to itself or to another.

A stack of the same size and construction as that serving the No. 1 building serves to carry away and dissipate in the upper atmosphere all fumes from the roasting ovens here installed.

Power Plant

In common with the remainder of the refinery, the power plant shows evidence of careful planning and considerable attention to future conditions. The equipment at present installed is capable of taking care of a considerable extension to the plant, and ample space has been provided for future extension both of the boiler house and turbine room.

The building is of the usual brick, steel and reinforced concrete power house design, and the equipment has been arranged in an attractive layout.

The main power house boiler room contain four Babcock and Wilcox standard water-tube boilers, each of 3,419 square ft. heating surface, set in two batteries. These boilers are built for a working pressure of 160 pounds per square inch, each being fitted with B. & W. superheater, which superheats the

bines operating at 8,500 revs. per min. steam about 100 degrees. B. & W. chain grate stokers are also fitted.

Two B. & W. boilers of special design are also installed for utilizing the waste heat from the reverberatory furnaces of the nicked refinery. These boilers are designed for a capacity of approximately 400 boiler horse power each, and are of particular interest as they represent the latest design in waste heat boilers developed from very extensive investigation into this class of work by the Babcock and Wilcox Company.

Coal and Ash Handling

Coal is received from the cars in a track hopper crushed in a Jeffry single-crushing roll, elevated, and conveyed overhead to a ssupended bunker, from which it is fed as required to the stokers.

The ashes are removed from the ash pits by ash cars running in an underground tunnel to the elevator and ash storage bin from which they are dumped into cars for removal.

One 6 ft. by 175 ft. reinforced concrete chimney conveys the products of combustion from the boilers in the power house. The waste heat boilers are served by two 5 ft. x 10 ft. reinforced concrete stacks.

Turbines and Generators

Two Ridgway-Rateau high pressure turbines furnish power for the direct connected d.c. generators, each of 1,000 kw. capacity. These turbines operate under 150 pound initial steam pressure, and 28 in. vacuum, and run at 1,700 revs. per minute.

The power house also contains two other turbo-driven units, these being high pressure blowers supplying air for the converters. Like the turbo-generators, these units are of Ridgway-Rateau make. The turbo-blowers are each of 15,000 cub. ft. capacity, and deliver air at 15 pounds pressure. They are connected to high pressure condensing turbines operating at 8,500 revs. per min.

The superseding of the reciprocating engine by the turbine in the large power plants has provided the means for the elimination of the cumbersome blowing engine. The high rotating velocities obtainable to-day are especially well adaptable to the driving of centrifugal blowers, and the turbo-blowers at this plant are much more economical of space than blowing engines of similar capacity would be.

The impellers are built up around a large diameter shaft with dovetail radial slots milled in it. The impeller blades are tapered in sections, being much thinner at the tip than at the root, and are driven into these slots, distance pieces being inserted between the blades in several stages. All turbines are equipped with Frahm tachometers, supplied by James Biddle, Philadelphia.

Condensing Equipment

Two No. 7 Westinghouse LeBlanc jet condensers, with individual air and circulating water pumps serve the turbo-generators. Each unit is fitted with a 31 h.p. steam turbine and reduction gear for pump drive. These condensers are each capable of handling 17,500 pounds condensate per hour, and maintain a 29 in. vacuum, with 40 degrees cooling water.

For the turbo-blowers two similar No. 5 units are installed. These are fitted with 21 h.p. steam turbines, and are capable of handling 11,000 pounds of condensate per hour, at 29.05 in vacuum with 40 degrees cooling water.

Electrical Features

The main switchboard supplies the plant load with direct current at 250 volts, lighting and other 110-volt services being supplied by means of a three-wire service operated by two 20 kw. motor generator balancing sets. I. T. E. circuit breakers. Weston indicating ammeters, and Sangamo watt-meters are installed on the generator and feeder panels.

Feed Water Equipment

The feed water is heated by exhaust steam from the various plant auxiliaries in Webster-Lea heater meter units. The heaters were supplied by Warren Webster and Company, Camden, N.J., and the Lea meters by the Yarnall-Waring Co., Philadelphia.

Two units were installed, one heater good for 5,000 h.p. equipped with Lea recorder, and having a capacity of 275,000 pounds per hour, and another unit similar in construction to the first and having a capacity of 1,500 h.p., or 100,000 pounds per hour. Both units are of extra heavy construction and were designed to withstand a back pressure of 10 pounds per square inch.

A two-inch venturi meter meters all feed water, and the feed pumps are of Lea-Courtenay make, direct-connected to Terry steam turbines of standard type. Owing to the horizontal parting of the casing, these turbines are very accessible for repair, and the fact that no oil comes in contact with the steam renders the use of an oil separator on the exhaust line to the heaters unnecessary.

MORE THAN 2,000,000 H.P. ELECTRIC ENERGY GENERATED IN CANADA

THAT there is upwards of 2,000,000 horse-power of electrical energy generated in Canada is demonstrated in the report on Electric Generation and Distribution in Canada about to be issued by the Commission of Conservation. The investigation into this subject has extended over a number of years and has been a most comprehensive one. Two of the principal points to bring out are the large part water-power plays in the production of electricity and the fact that over three times as much power is produced by privately-owned plants as by those publicly owned.

Water Power Predominates

There are, according to the report, 565 electric generating plants in Canada, with an aggregate capacity of 2,107,743 h.p. These supply 752 distributing systems, which serve 973 localities. Classified according to the prime-movers used, these plants are divided as follows:

270 hydro-electric, aggregating	1,806,618 h.p.
201 steam plants, aggregating	288,202 h.p.
49 gas plants (nearly all producer-gas), aggregating	8,157 h.p.
45 oil or gasolene engine plants, aggregating ...	4,766 h.p.

These figures give a very fair idea of the power situation, and show the unquestionable predominance of water-power. In the Maritime Provinces, steam and water-power predominate with the former in the ascendancy. In Quebec, Ontario and eastern Manitoba, water-power is the dominating source of power, every large centre and most of the smaller ones being supplied by electricity produced from water-power. In the Middle West, large plants are steam operated, while the smaller ones use internal combustion engines. In British Columbia and western Alberta, water-power again predominates, but the generous coal supply in certain districts also permits considerable steam operation.

In the large hydro-electric installations, the report says, the type of plant is of the most up-to-date and substantial construction, but the same, unfortunately, cannot be said of many of the small plants, particularly the older ones. Old, leaky dams and inefficient types of water-wheels in bad repair are often the real causes of shut-downs attributed to lack of water. Likewise in the large steam plants, efficiency is shown, but this is not generally true of the smaller ones. For the prairie provinces, where fuel and the cost of generation are high in price, the report suggests that it would be more economical to generate electric power in large central steam plants and distribute it over transmission lines.

More Privately-Owned Plants

The report shows that there are 207 municipal or publicly-owned plants of 452,508 h.p. capacity and 358 plants privately owned with a capacity of 1,655,235 h.p. The Niagara system of the Ontario Hydro-Electric Power Commission is the largest under public ownership. It has a load of over 201,000 h.p., supplies 120 municipal distributing systems and serves an area of 210 miles long by 85 wide. The largest privately-owned system is the Shawinigan in Quebec, with a load of 205,000 h.p. supplying 76 distribution systems and serving a triangular area with a base of 140 miles and a height of 75 miles.

The largest hydro-electric development is 488,800 h.p., in the three large power plants at Niagara. The large installations are not all confined to this site, however, as there are, in addition, 5 plants of over 100,000 h.p. and 36 plants of over 10,000 h.p. capacity. The large single plant is the Ontario Power Co., now operated by the Ontario Hydro-Electric Power Commission at Niagara, with a total capacity of 211,300 h.p. The largest single unit thus far installed in Canada is 20,000 h.p., at Grandmere, Que., though the Ontario Hydro-Electric Chippawa plant will contain units of 50,000 h.p., while future plans contemplate the use of 100,000 h.p. units.

The average head of water utilized is not exceedingly high, but many large hydro-electric plants operate under fairly high heads, such as 140 to 180 ft. at Niagara, 145 ft. at Shawinigan, 83 ft. at Grandmere and 400 ft. at the Coquitlam-Buntzen plants near Vancouver. The highest head in eastern Canada is 540 ft., at the 8,000 h.p. plant at Eugenia Falls, Ont., while, in the West, a head of 1,820 ft. is utilized at Britannia Beach, B.C., where the development also provides a total head of 3,530 ft. in two steps of 7,450 ft. and 2,080 ft. for the direct operation of other machinery. On the other hand, one of the largest plants recently installed at Cedars, Que., operates under a head of 30 feet.

The 26,667-horse-power plant at Hamilton, Ont., is the largest steam-power plant in Canada and is used as an auxiliary. The 14,234-h.p. plant at Edmonton, Alta., is the largest steam plant operated continuously.

Storage Reservoirs Increasing

No less than 59 plants report the successful operation of storage facilities to provide for increased flow at low-water periods. Among Government undertakings of this nature may be mentioned the three large reservoirs at lakes Timiskaming, Kipawa and Quinze to regulate the flow of the Ottawa river; La Loutre reservoir on the St. Maurice river; lake St. Francis dam for the St. Francis river, Que.; the extensive system of small conservation reservoirs on the Trent river, Ont.; lake Minnewanka, on the upper waters of Bow river, Alta., and the reservoirs on Jordan river and Goldstream, near Vancouver, B.C. Most satisfactory results have been obtained from storage undertakings, the capacity of plants being frequently doubled or more than doubled.

The utilization of the large peat areas in the north part of Jutland is receiving much attention. The area is said to be as much as 28,000 acres, which, according to "Ingenioren," could be completely drained by gravitation, and the total contents might be equivalent to 23 million tons of coal. It is suggested that the peat could be utilized (1) as air-dried briquettes used for heating the boilers of adjacent electrical supply works; (2) as machine made briquettes sold for general consumption as far away as the cost of transport will allow; (3) as peat litter to be sold to neighboring farmers; (4) the lower parts of the bogs should be reclaimed and used for agriculture. The heating value of the peat is assumed to be half that of coal. The works required should be executed by private enterprise, aided by the State, and the cost of reclamation would amount to £50,000. The first 9,000 acres could be dealt with in twenty years, and the rest of the land occupied in course of time as the peat is cleared away.

Historical Development of the Steam Turbine--IV

The Last of a Series Dealing With Development of the Turbine—Coupling Design Has Improved Since the First Turbine Was Built, and Lubricating Systems Are Now a Most Important Feature

Couplings

In the earliest machines, the turbine and generator shaft were each provided with a square formed in the end of the shafts over which fitted a loosely fitting sleeve. This was subsequently replaced with a claw-type coupling, Fig. 34. This coupling is of the so-called flexible type which, however, does not permit of successful operation with material misalignment of the turbine and generator shafts. With misalignment there is a slight variation of angular velocity which, on account of the inertia of the revolving parts, causes a heavy intermittent stress on the driving horns, each horn in turn having to accelerate the masses slightly at each revolution. There were a few cases where breakage occurred, although the stresses due to normal operation were quite low. Of course, the greater the length of the coupling between the sets of driving horns the more truly flexible it becomes.

In the latter type couplings shown in Fig. 35, circular driving pins having considerable overhand are employed, thus permitting a slight flexibility of the pin itself, that is, they may deflect slightly without strain. No breakage has occurred with this design.

Lubricating Systems

All turbines have been provided with lubricating systems, operated by pumps directly driven by the turbine. In all but the smallest sizes, this is relayed by a separate steam-driven pump, which is for use only in starting and stopping. With time, however, the lubricating

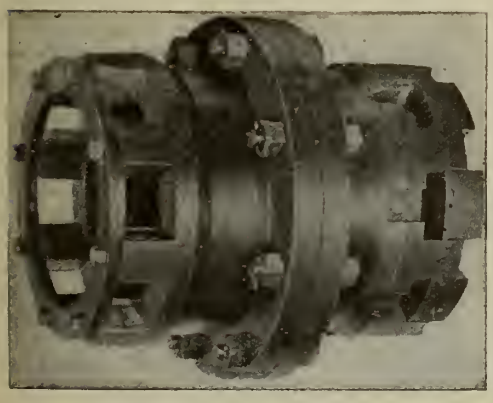

FIG. 34—CLAW TYPE COUPLING.

system has become more elaborate. It is generally recognized that the life of the oil is much increased by an ample reservoir. The longer the rest the oil has between the times of actual use in a bearing, the better; hence the capacities of reservoirs have been materially increased, a 20,000 kilowatt turbine having a 20 barrel oil tank. Later machines are provided with elaborate strainer systems which may be cleaned while the turbine is operating.

A system of fractional filtration is coming into general use, there being provided in the power house a first-class filter system of moderate size, capable

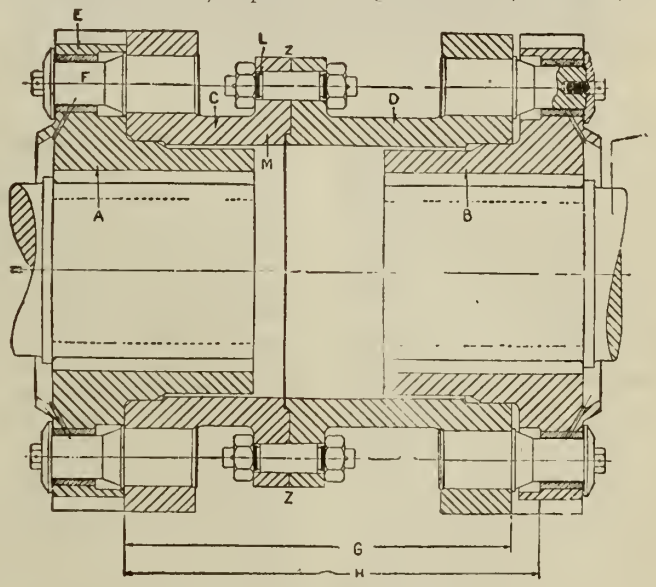

FIG. 35—DETAIL OF MODERN COUPLING.

of filtering continuously a few per cent. of the oil actually being used. The oiling system is provided with an overflow arranged to drain out from the bottom of the reservoir the dirtiest oil. A supply of clean, pure oil, commensurate with the capacity of the filter system, is then delivered into the turbine system; the same amount of dirty oil overflowing to be refiltered.

Oil coolers or their equivalent are always necessary. It has been the custom of the Westinghouse Company always to employ a separate cooler. The practice of water cooling the bearing itself, or of embedding cooling coils in the babbitt, while highly efficient from the standpoint of heat transfer per unit of surface, has never been resorted to because of the impracticability of cleaning. A modern cooler is shown in Fig. 36, the water making many passes at high velocity through the tubes, the oil circulating outside the tubes. The cooling surface merely lays in a cast-iron box, the water connections being more or less flexible. Proper provision for expansion is evident as it is the means by which the whole element may be lifted out for cleaning.

Oil is used at a temperature conducive to any chemical action; it therefore must have no tendency to turn acid, which generally precludes the admission of any animal or vegetable oils. It is found that some higher viscosity oils, while they may contain nothing but pure mineral stock, have a tendency to emulsify. This is particularly true in cases where the reservoir system is not large and the oil gets insufficient rest. A viscosity as low as 150 secs. Saybolt at 100 degrees Fahr., is satisfactory for turbines. In the case of geared units, however, a viscosity of 250 to 350 secs. Saybolt at 100 degrees is recommended; the turbine itself operating equally well with this higher viscosity, the only difference being a slightly higher bearing temperature and a little more cooling required. The ideal lubricant is the fluid having the greatest adhesion and the least cohesion. The requirement of the bearing is that the relatively moving surfaces be adhered to by the fluid, the fluid itself being sheared between the surfaces, a definite film adhering to each surface. The work of the bearing, due to the bearing losses, depends on the resistance to this shear, which is a function of the viscosity. Inasmuch as the vicosity becomes less with increasing temperatures, bearing losses may be maintained at a minimum by operating with high oil temperatures. Decreases of viscosity with the increase of temperatures reduces the losses, so unless there is something the matter a bearing will reach a definite temperature and stay there. It is self-regulating in that respect. While turbines operate well with oil temperatures as high as 160 degrees Fahr., no attempt is made to state what may be regarded as limiting temperature, or in what respect the life of the oil is reduced by continued operation at high temperatures. Inasmuch as the oil consumption of a turbine, after the system has once been charged, is practically nothing, the question of price at the expense of quality

and suitability should not receive consideration.

Exhaust Passages

More attention is being given to the exhaust passages of turbines, that the steam may leave the turbine without eddies in the exhaust chamber. In older designs it was not uncommon to find hot and cold spots with the turbine operating under light loads, and particularly on a change of vacuum, doubtless inducing considerable temperature strains. Some later large machines are projected with what may be termed "stream line exhausts," the steam being divided up as it leaves the last row of blades into a number of easy curved passages leading to the exhaust opening.

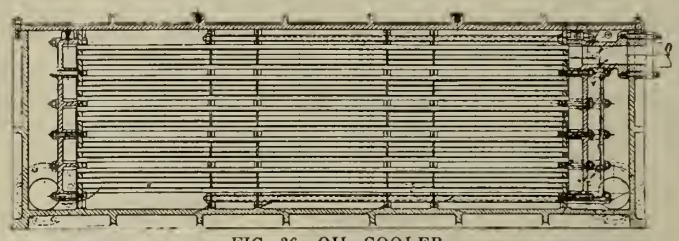

FIG. 36—OIL COOLER.

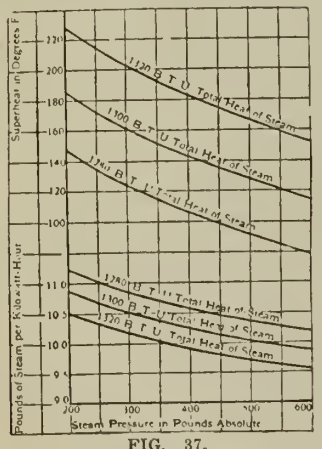
With high-speed machines the exhaust passages have greater physical dimensions than anything else about the machine, the turbine almost appearing to be all exhaust chamber, so any further reduction in diameter in the inherent turbine parts will not materially affect the dimensions of the whole turbine.

Progress and Future Possibilities

Discussion of the general progress of turbine development in the past is not complete without reference to the possibilities of the future. It is plain that with turbines of large size, which deliver to the switchboard 76 to 80 per cent. of the theoretical energy available from the steam expanding between the limits specified, further improvements in the turbine itself will not materially raise this efficiency, and that further improvement in central station economies must be looked to from causes other than the steam turbine. This is a subject of the greatest importance in view of the rapidly increasing cost of fuel, and justifies considerably more capital expenditure for economizers and other plant apparatus which will reduce fuel cost.



Superheat in Degrees F
Pounds of Steam per Kilowatt-Hour
Steam Pressure in Pounds Absolute
1120 B.T.U. Total Heat of Steam
1300 B.T.U. Total Heat of Steam
1240 B.T.U. Total Heat of Steam
1280 B.T.U. Total Heat of Steam
1100 B.T.U. Total Heat of Steam
1150 B.T.U. Total Heat of Steam

FIG. 37.

Attention at the present time is being directed to employing higher boiler pressures, viz., pressures as high as 600 pounds. To-day 200 pounds pressure, 200 degrees Fahr., superheat is regarded as a more or less every day operating condition for large plants. Steam is generated at 600 pounds pressure, having exactly the same heat content as that contained in 200 pounds pressure and 200 degrees Fahr. superheat will have a superheat of approximately 128 degrees Fahr. This expanded to 29 inches of vacuum is theoretically capable of giving 13 per cent. more energy than when generated at 200 pounds. Doubtless, when operating under these conditions, the turbine will be of lower efficiency. The high pressure element will be less efficient on account of the great density and the small volume of steam, and on the other hand the low-pressure elements will be less efficient because of the great amount of water precipitated by the steam expansion from the high pressure, introducing a brake in the turbine. However, it is reasonable to suppose that the turbine will avail itself of at least 50 per cent. of this 13 per cent. possibility, producing a net saving of 6 or 7 per cent. What may be expected to be derived from higher pressures is exhibited in Fig. 37, plotted for various pressures.

Another source of improvement of performance in large multiple-cylinder machines may be obtained by intermediate reheating, the steam expanding from a high pressure and superheat through a high-pressure element to a pressure of say 40 pounds absolute, where nearly all the superheat has disappeared, the steam then being passed through a separately-fired superheater and raised to approximately its original temperature, thus giving a nearly dry cycle to the whole steam expansion. The addition of an intermediate reheater to such an installation would be expected to secure an improvement in total b.t.u. supplied, of 5 per cent. Until lately, however, the capital expense involved would hardly have been warranted.

Much more than formerly, attention is being given to the subject of feed water heating, and means are available for providing a heat balance between the feed water heating system and the main turbine unit, valves being provided which will take steam from the turbine whenever there is a deficiency of auxiliary exhaust steam for heating feed water and take steam from the heating system when the feed water heater is incapable of condensing all of the exhaust steam from the auxiliaries. Valves are also available which, when the conditions demand, will take steam from a higher pressure stage of the turbine in one case and admit steam to a lower stage in the other.

A heat balance system has been proposed, employing electric motors for driving the auxiliary machines, and these in turn operated by a special generating unit, the generator being driven both by a non-condensing steam turbine, an electric motor operated from the main busbars, the flow of steam to the turbine being controlled by the pressure in the exhaust and hence by the needs of the feed water heater. At times of excessive demands for feed water heating the motor may give energy to the system and conversely when there is a small demand for steam for heating feed water, the energy for driving the auxiliaries will, in part, come from the main units. The auxiliaries, being motor driven, have the advantage of reducing the general dirtiness, heat, and overcrowding to be found in the basements of many power plants on account of the steam and exhaust piping of the many small turbines. The general prejudice against electric motors and other auxiliaries would seem to be giving way in view of greater ruggedness of electric motors and the safety of their circuits. The heat energy actually required to operate the auxiliaries with such a system would be far less on account of the better performance of the large turbine unit as compared with the number of small non-condensing auxiliary turbines in spite of the electrical losses involved.

1200 B.T.U. Total Heat of Steam
1300 B.T.U. Total Heat of Steam

FIG. 38

Further economy may be expected by making more extended use of the economizer. Until lately it has been considered difficult to operate economizers successfully if the feed water is admitted to them at a temperature much below 200 degrees, because of corrosion of the surfaces and the condensation of tarry compounds from the fuel. It is probable that in the future economizers will operate well with the water entering them at 120 degrees or thereabouts, the water being heated to this temperature by a fewer number of steam-driven auxiliaries or by the employment of electrically-driven auxiliaries entirely, and bleeding the main turbine at a stage where the pressure is commensurate with that temperature.

The present time is a very important period in the development of the steam turbine. A large number of big units have been built ranging in size from 25,000 to 60,000 kilowatts. Those built by the General Electric Company are of the impulse type, those by the Westinghouse Company entirely of the reaction type, and sometimes a combination of both types, where the complete expansion is carried out in a single cylinder. Of the Westinghouse machines, the increased reliability obtained by dividing the steam expansion in separate cylinder structures is recognized. Some have been arranged with the high and low-pressure cylinders arranged tandem fashion, driving a single generator. Others are arranged "cross compound," each turbine element driving a separate generator. The very largest sizes are of the three element design, comprising one high-pressure turbine with a low pressure on either side, each of the three elements having its separate generator.

Some of these units are now in operation, and within another year a great many will be in service. Some of them will be tested for steam efficiency. All of them will give evidence as to their reliability of operation and accessibility for inspection and repairs. The multi-cylinder turbine certainly seems to have much to commend it if there is anything in the thought that with increase in the capacity of the prime mover there should be a corresponding increase in reliability. These very large units, if built in a single cylinder structure, impose grave problems of design, for as the structure becomes larger, the more likely it is to change shape under the varying temperatures within its walls. Also, the hazard is introduced of using higher grade materials to deal with higher stresses, with all the uncertainty which that question involves in the actual securing and testing of such materials, with absolute knowledge that the quality of the test specimen will be secured approximately in the finished piece.

We then have the increasingly imminent question of dealing with higher steam temperatures, which does not make the design of turbines any easier as is well proven in several recent instances, so if we take advantage of the fact that in size alone resides an ability to achieve higher efficiency, then it would seem that the uncertainties of design and construction as regards heat stresses, as well as centrifugal stresses, can best be removed by introducing no new questions. Let us have the high efficiency that comes with large size as bringing us within well-tried practice, dealing with no special materials, avoiding widely differing temperatures within the same structure, keeping the high temperatures within the relatively small high-pressure element, and be ready also for the still higher temperatures of the future. The multi-cylinder arrangement occupies more room, measured in the width of the unit, but less in length; however, the turbine room space in this respect is not a problem in most stations. They have the advantage, previously pointed out, that the turbine elements are sensible of being operated separately in the event of derangement of either one of them. Automatic apparatus is provided, when demanded, for any two of the three turbine elements continuing to carry load, should the one be taken out of service, either by the opening of the circuit-breaker or by tripping the emergency stop. The compound unit costs more money, but not prohibitively more, if the construction behind its adoption is justified by experience. In view of the present power house costs there would seem to be no economic need of reducing the cost of the turbine units below the amount required to make them as nearly perfect as possible. It is hoped that the time is not far distant when the turbine designer will not have to initiate quite so much as he has in the past, that on the operating side the engineers will test their turbines more generally and will know precisely what results they give in steam consumption, and will take a stronger position respecting the mechanical features of design, details of operating convenience, etc., much as they used to when they dealt with the subject of Corliss engines, and recognize and give consideration to better detail design of not only the turbine itself, but its appurtenances.

From all that has been said it is plain that the progress in the construction of turbines has not been to reduce intrinsic cost. The increased reliability, while sometimes secured by more skilful design, and at even a reduction of cost, generally however involves a greater cost. The higher operating conditions, pressure, superheat and vacuum, each involves greater expense. The higher vacuum calls for larger low-pressure blade arrears, as well as an increased number of turbine elements. The higher pressures and superheat both involve more turbine elements, and also preclude the use of cast iron for the high pressure portions, adding materially to the cost of gears, etc. Competition calling for the highest performance, has brought about the employment of higher design coefficients which introduce still another element of increased cost. The increase in rotational speed for a given size machine is about the only item besides improved manufacturing processes that have enabled manufacturing costs to be reduced.

In spite of this, the price (under pre-war conditions) of large turbine generating units has been reduced to approximately 40 per cent. of the cost of the earlier large turbines of 5 000 kilowatts or thereabouts. The efficiency ratio has been increased in this size approximately 8 per cent. Considering the larger sizes that now obtain, the cost per kilowatt is further reduced and efficiency ratios have been improved 12 per cent. Actual heat consumption of b.t.u. supplied at the throttle has shown a reduction of 24 per cent. between the 7.500-kilowatt turbine of 1905 and the Interborough turbine of 1914.

Comparison of steam engine performances are, however, incomplete without consideration of capitalization, depreciation, etc. Assuming the cost of steam at 15 cents per thousand pounds, a load factor of 75, and 15 per cent. for fixed charges, a saving of 33 per cent. is produced by the latter of the above two machines.

To make similar comparison between a modern large turbine installation and the best performance of reciprocating engines, assume:

	Turbines	Engine
Initial cost per kw. of the generating units	$8.00	$40.00
Fixed charges, per cent. .	.15	.15
Pounds steam per kw.-hr.	.11	.17
Cost of steam per thousand pounds at 220 pounds, 150 degrees supht., 175 pounds dry sat.	.15	.14
Load factor	.75	.75
Cost of foundations per kw.	.50	2.50
Cost of condensers per kw.	3.50	2.50
Cost of engine room personnel, not including executive administration, per kw. per year .	0.61	1.57
Oil and engine room supplies per kw. year	.10	1.34
Total cost per kw. per year	$13.34	$25.29

The modern large turbines have therefore accomplished a saving over the best reciprocating engine installation of approximately 47 per cent. The cost of energy has been no doubt reduced to one-half if consideration is given to reduced size of buildings, etc.

In the early days of the oil-immersed transformer, attempts were made to use some of the fixed oils, such as resin oil, linseed oil, cotton-seed oil; because it was found that these oils had a higher dielectric strength than the straight oils at that time on the market. It was soon found, however, says Mr. W. S. Flight, in the "Electrician," that the fixed oils gave trouble in the transformers due to the formation of carbonaceous deposits, and about the same time it was found that straight oils, free from impurities and all traces of moisture, had as high dielectric strength as the fixed oils. As the latter are not so liable to form deposits and are cheaper, their use has continued ever since. It has been found that the voltage at which a definite thickness of oil will break down depends more upon the amount of moisture and other impurities in the oil than upon the type or nature of the oil. When tests are carried out on clean moisture-free oils it is found that those having a low viscosity have a higher dielectric strength than those of higher viscosity.

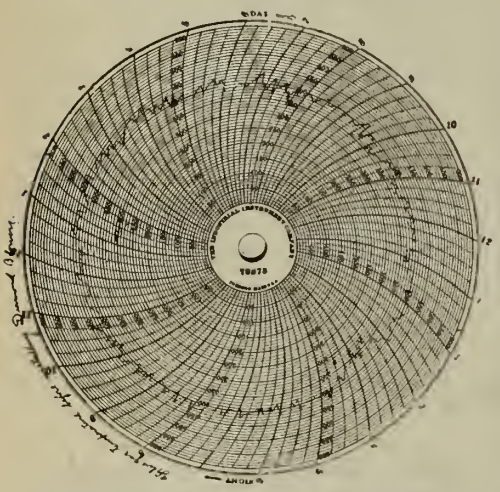
Power Plant Management; Heat Absorption

How Heat is Transmitted—Effect of Scale Influence on Heat Transmission—Soot—What it Is—How it Acts—Hand Cleaning Not Effective—Tests on Soot Blowers

By ROBERT JUNE

THE war has been won, and the tension under which the power plants of Canada have been operated is somewhat relaxed—that is, theoretically. Actually, the reduction, to date, in demands upon our industrial power plants is merely relative; that is, instead of being called upon to deliver steam to 200 per cent. of their normal rating they are now permitted to dawdle along at 180 per cent.

Incredible as it seems, the war has nearly doubled Canada's economic resources. It has added 200,000 trained workers, a number of new blast furnaces, steel mills, and many general manufacturing plants. As a result of its demands, very large extensions have been made to our textile, paper machinery, brick and clay, ice and refrigerating plants, and so on all the way down the line of industry. In



FLUE GAS TEMPERATURES BEFORE INSTALLATION OF MECHANICAL SOOT BLOWERS, PLANT OF AMERICAN HOIST & DERRICK CO.

addition to keeping these plants busy, we have the varied wants of an immense new shipping industry to care for. Unfortunately, proportionate extensions have not been made—perhaps have not been possible—to our boiler plants, whether isolated or central station.

Inasmuch as it is a foregone conclusion that we will capitalize our new war-given resources, we are confronted by the following conditions:

First.—The coal shortage will continue. Although the coal situation may not attract so much attention this year as last because the shortage will be less pronounced, there is no possibility of our mining or securing as much coal in 1919 as we can, or will want to, use.

Second.—If many needed power plant extensions are authorized, and boiler manufacturers work to the limit of their productive capacity in 1919, there will still be a boiler shortage, which, of course, means the existing plants must continue to be driven at high ratings.

I have gone into the existing situation at some length because I am in close touch with it and have some reason for believing that it is not thoroughly understood, and also because it places an obligation upon every power plant operator to conserve coal in the utmost practicable degree by running his boilers on the most efficient basis.

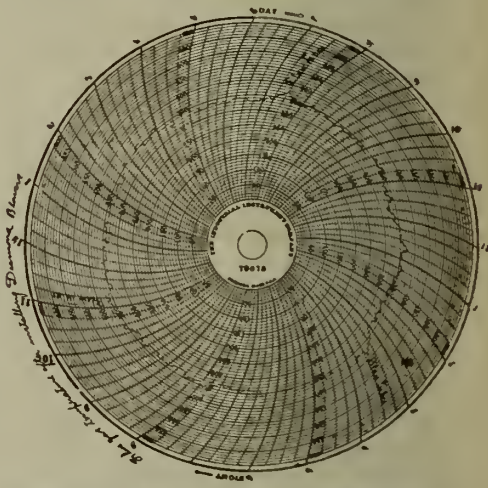
"Cleanliness is next to Godliness," says the age-old proverb. Certainly, we moderns know that it is also next to efficiency—is indeed part and parcel of the latter quality. Nowhere is this truer than in the operation of a steam boiler. How clearly the United States Fuel Administration recognized the fact is shown by its assignment of a value of twelve points out of a possible one hundred, to clean boiler-heating surfaces, in determining the rating of power plants.

How Heat is Transmitted

Heat is transmitted to the water within the boiler by three processes—radiation, convection and conduction. The generally accepted theory of the part each of these processes plays is illustrated in Fig. 1. It will be seen that radiation originates in the fuel bed and hot furnace walls, convection in the hot travelling gases, and that conduction is a function of the metal of the boiler. It is furthermore shown that the heat has to penetrate five layers of interfering substances; namely, a film of dry stagnant gas, a layer of soot, the metal of the tube, a layer of scale, and a film of dry steam.

With the exact or relative values of radiation and convection we are not here concerned, except to observe that on account of the limitations of refractory materials there is no great hope of increasing furnace temperatures in the immediate future, and that if we are to increase boiler capacity it will have to be through other agencies than convection. Inasmuch as we can greatly increase the amount of boiler surface exposed to radiation, this is the principal line along which we are to look for improvement in boiler and furnace design.

Hardly less important, however, is the necessity for devising means of dispersing the dry gas and steam films on either side of the tube. These films are extremely poor conductors of heat. It has been found, as the result of experiments by Professor Nicholson and the U.S. Geological Survey, that by establishing a powerful scrubbing action between the gases and the boiler plate, the non-conducting film of gas can be torn off as rapidly as it is formed, thus bringing new portions of the hot gases in contact with the tube, and thereby



FLUE GAS TEMPERATURES AFTER INSTALLATION OF SOOT BLOWERS, PLANT OF AMERICAN HOIST & DERRICK CO.

greatly increasing the rate of transmission. Similarly, the faster the circulation of the water the greater will be the scrubbing action tending to remove the bubbles of steam from the wet surface, and the more rapid will be the transfer of heat from the tube to the water. By filling up the tube of a Cornish boiler with an internal water vessel, leaving an annular space of only one inch around the latter, Professor Nicholson found that it was possible to drive the boiler to 800 per cent. of normal rating, with a flow of gases of 330 feet per second. This flow, which is 8 to 10 times the average, was maintained by a fan, utilizing about 4½ per cent. of the total power generated.

I have mentioned these factors in heat transmission because they presage certain important improvements sure to come in boiler and furnace design, and it is the duty of prospective boiler purchasers to be informed of them, to discuss them with boiler manufacturers, and to lend every encouragement to the latter in their work of devising cheaper means of steam production.

Scale

Coming now to practical questions of every day operation, we find that the formation of scale is only in a limited

Editor's Note.—This article, one in a series on "Power Plant Management," by Mr. June, deals with the all-important problem of maintaining clean heating surfaces in the boiler. The need of stringent economies in boiler operation makes the question of scale and soot removal of direct interest to every power plant operator.

degree a factor of design, being chiefly dependent upon the rate of driving and the nature of the scale-forming ingredients in the feed water.

That the formation of scale should be absolutely prevented by purifying the feed water, or that it should be removed as rapidly as it forms by scale cutters, or "tube cleaners" as they are called, is one of the most elemental facts in efficient boiler-room operation. The loss in conductivity, due to the presence of scale, has never been reduced to a rule or formula, depending upon the thickness, or the degree of hardness and thickness, or the chemical composition of the scale. The percentage of loss can only be determined in each individual case by actual tests.

Table I gives the results of a number of tests of loss due to scale, made at the University of Illinois. It will be seen that the results are so varied as to prevent any detached conclusions—but that they do point unmistakably to the very great loss, running from 2 per cent. to 19 per cent. caused by scale—and that they also point to the previously stated very great necessity of absolutely preventing scale formation, or failing this, its removal as soon as formed.

TABLE I.
INFLUENCE OF SCALE ON HEAT TRANSMISSION.

No.	Character of Scale.	Thickness of Scale.	Decrease in Conductivity due to Scale. Per cent.
1		.02	Hard, dense 9.1
2		.02	Hard 2.02
3		.033	Soft 4.83
4		.033	Very hard 3.5
5		.038	Medium 4.03
6		.04	Soft, porous 6.82
7		.04	Hard, dense 3.07
8		.042	Very soft 9.54
9		.047	Hard 2.75
10		.065	Medium 2.39
11		.07	Soft 2.38
12		.07	Hard 4.43
13		.085	Soft, porous 19.0

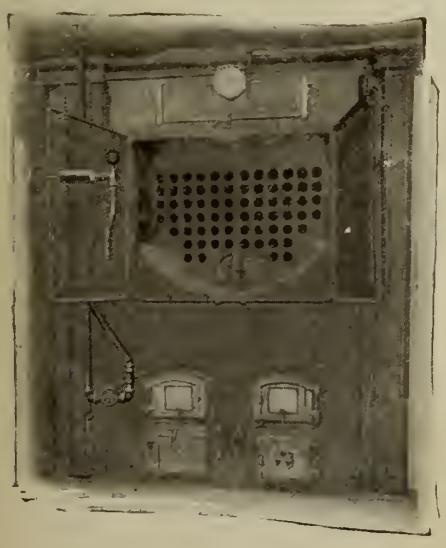
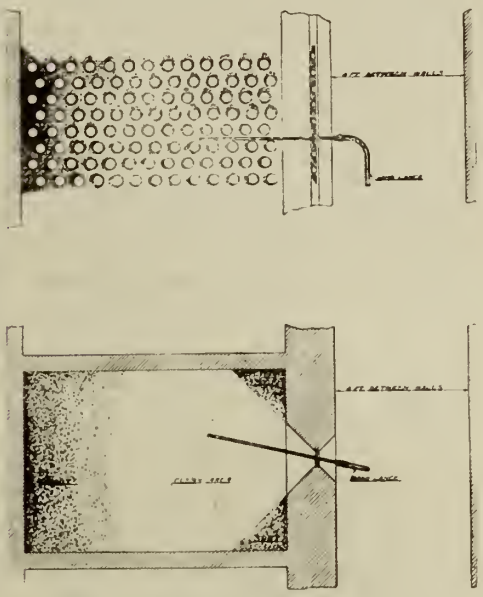
16		.13	Hard, dense 6.75



DIAMOND SOOT BLOWERS ON RETURN TUBULAR BOILER.

Soot

Of all sources of preventable waste, that of the formation of soot on the fire surfaces of the boiler is the most troublesome. Air leaks in the setting may be found and be hermetically sealed. Losses due to radiation may be largely eliminated by proper insulation of the pipes, and losses caused by excess air drawn through the grates may be done away with in a large degree by the installation of stokers and draft gauges. The formation of soot, however, cannot be stopped by any permanent means. It is an ever-present source of trouble. Its deposit on the fire surfaces of the boiler is an ever



WHY THE HAND LANCE DOES NOT CLEAN THE BOILER

continuous process.

Soot is all but the best insulator known. In non-conducting properties it has been proved to be more than five times as effective as fine asbestos. More heat would be transmitted to boiler tubes through a full one-inch wrapping of asbestos than through one-fifth inch coating of soot. The table following is from Kent's pocket book.

TABLE II.
WATER HEATED THROUGH VARIOUS SUBSTANCES.

Thickness of each substance .....1 inch
Temperature applied to each.....310 deg. Fahr.
Temperature increase of water in each case ..... 10 deg. Fahr.

	Substances	No. lbs. of water heated.
1.	Loose wool	8.1
2.	Loose lampblack (soot))	9.8
3.	Hair felt	10.3
4.	Carded cotton wool	10.4
5.	Fine asbestos	49.0

A perfectly clean boiler tube, one-eighth inch thick, will transmit forty times as much heat as will a tube covered with one-inch thickness of soot.

The loss in heat conductivity of boiler plate, due to soot deposit, may be noted in the following table:

TABLE III.

Thickness of soot.	Per cent. of loss.
Clean pipe	0.0
1-32"	9.5
1-16"	26.2
1-8"	45.3
3-16"	69.0

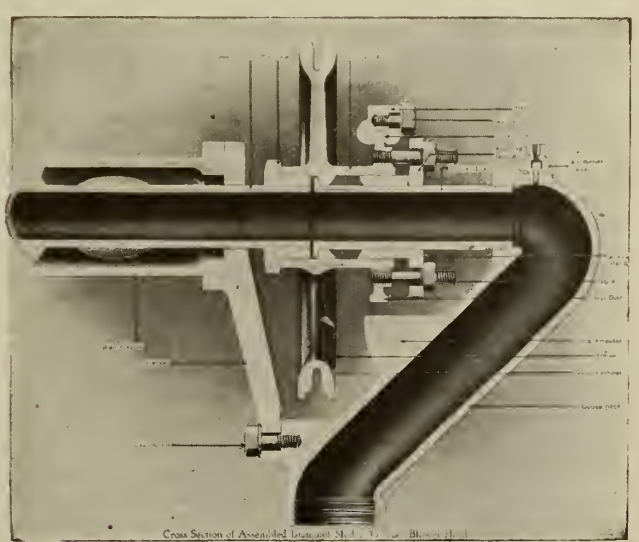
Fortunately soot does not collect on all surfaces of a boiler in the same proportion. Some portions may be fairly clean while others are thickly coated. This does not lessen the fact that there is a wasteful expenditure of fuel and heat wherever a portion of the tubes are coated.

What Soot Is

The principal constituent of "pure soot," or lamp black, is carbon. Mixed and associated with this carbon are various tar products and acids.

Soot, as found in steam boilers, varies considerably in appearance and composition, depending upon the grade of coal burned, conditions of combustion, and the part of the furnace from which the sample is taken. Nearest the fire the deposits formed consist largely of ash. Analysis of samples of soot taken from the first pass of a boiler shows in addition to the "pure soot" the presence of silica, alumina, iron oxide, various alkalis and sulphur dioxide.

In color, soot varies from black to grey, greyish white, greyish green, greyish blue, brown, and reddish brown.



CROSS-SECTION OF DIAMOND MODEL G SOOT BLOWER HEAD.

In all but the coolest portion of the setting soot is usually gritty in texture. The grains may be as large as medium sand, or as fine as cigar ash. These particles are in a plastic state when they leave the furnace, and striking the lower portion of the boiler they adhere to the tubes.

If this deposit is not removed frequently it quickly increases in amount and changes in character. The carbon burns out in part and the mass cements together. The repeated reduction in heat-absorbing surface increases the temperature of the flue gases, so that the process of cementation is continuous and constantly increasing in intensity. An extremely hard, clinker-like formation results. In a short time the space between the tubes in some portions of the boiler is entirely blocked, thus materially reducing its capacity. In this condition mining operations alone will remove the deposits.

A bad feature of these deposits is that if they are allowed to remain, the corrosive action of the various constituents of the soot is exceedingly apt to cause leaky tubes. Under the influence of heat, a ferrous carbonate is formed. The excess of air that is always present brings free oxygen in contact with the ferrous carbonate and the reaction produces ferric oxide and carbonic acid. Carbonic acid, particularly in the presence of free oxygen, acts very rapidly on the metal of the boiler. Another source of corrosion is the sulphur dioxide in the soot which changes first to sulphurous acid and then to sulphuric.

Only the boiler-insurance companies know how many boilers are condemned annually as unfit for operation, years before their natural period of service would terminate. That the number is very high we know, for cases are constantly coming to light.

Hand Cleaning Not Effective.

It is a mistake to think that soot can be removed by the hand-hose method (using steam, through rubber hose and nozzle). The use of this system arose in the sheer necessity for removing some of the deposits from the tubes. It is admittedly an inefficient and expensive process as well as being an extremely disagreeable and, to a certain extent, dangerous task.

Two men are required, one close up to the boiler setting, frequently on a ladder (a delightful position on a hot summer day) and the other at the steam valve. The time employed is usually from 20 to 30 minutes. The nozzle is inserted, the spray of steam goes into the boiler, but whether it reaches all of the soot-covered parts of that section the fireman doesn't know. There is a large section near the cleaning door which he cannot reach at all. He is using a large supply of steam and he is letting an immense amount of cold air into the furnace. When he moves to the next location he will blow some of the soot back.

Says the author of "Furnace Efficiency":

"I was talking one time with the manager of a very modern power plant in the very modern city of Minneapolis. We got around to the subject of soot and the engineer said: 'I will show you that we keep our boiler tubes clean.' He raised the slide from one of the blow holes at the first pass in the boiler. There was a good light from the furnace just below the tubes and we had a fair view of them. They were reasonably clean. We then went to the back pass of the boiler but there was no light from the furnace there and we could see nothing. While the engineer was in search of a light I found a piece of gas pipe about six feet in length, and thrust this through one of the blow holes in the last pass and across the tubes of the boiler. I could tell by the feeling of the pipe that there was a surprise in store for my engineer friend. The flashlight showed furrows an inch deep where I had plowed with the gas pipe across the top of the tubes.

"Now, it is evident that the man who had charge of cleaning these tubes had not finished his job. He had blown soot from the first pass back into the second and from there to the third. Then he had stopped. Now, if things like that can happen in a well-regulated plant, what can we expect to find in plants that are not regulated?"

To clean off soot properly all of it should be blown off from the tubes. To blow it from one locality to another does not help much. It is no uncommon thing to find soot so thickly packed into the corners, along the side walls of a water boiler that you could use a hoe and shovel in removing it.

You want your boiler tubes to conduct heat as rapidly as possible to the water within the tubes. If you want to keep up steam when the soot piles up you will have to pile in more coal.

The Five Essentials in Preventing Soot Waste

The five essentials in preventing waste are:

1.—Frequency in cleaning in order to minimize the cumulative effects of increasing deposits. Tubes should be cleaned three to six times a day.

2.—Thoroughness in cleaning, in order to maintain high furnace and boiler efficiency, and prevent the destructive corrosive effects of soot accumulation.

3.—Availability of system; the soot-cleaner system should be instantly available, automatic in action, capable of rapid operation

4.—Durability of system; the blower units should be so designed and constructed that they will withstand the stress of hard service when placed in the hottest portions of the boiler without necessity for frequent repair or replacement.

5.—Economy of operation: The soot-removing system should require less steam and labor than hand blowing; it should be so installed as to prevent the entrance of cold air into the furnace during its operation; it should pay for itself from an investment standpoint.

Soot Blower Tests

The following extract is an excerpt from a report by J. A. Moyer, member A.S.M.E., professor of mechanical engineering, Pennsylvania College, covering a comparative test on a B. & W. boiler at the college power house, equipped with the Diamond soot-blower system.

The comparison was made, as regards operation, by making two tests with the usual method of hand cleaning the tubes with a steam nozzle, blowing them off every twelve hours. A second test was made when the Diamond soot blower was used for cleaning the tubes every three hours. Clearfield coal, having a heating value of approximately 13,650 pounds B.t.u. per pound of dry coal, was used in all of these tests. The actual heating value was determined with an oxygen bomb calorimeter for each test and the efficiency then calculated on this basis. Duration of tests one and two, was approximately eight hours, while tests three and four were run for 24 hours.

Load Conditions Good.	Test No. 1 Without soot Cleaner	Test No. 2 With soot Cleaner
Water evaporated per lb. of coal as fired, lbs.....	8.06	8.72
Equivalent water evaporated from and at 212 deg. per lb. of coal as fired, lbs...	9.50	9.97
Equivalent evaporated from and at 212 deg. per lb. of dry coal, lbs.	9.61	10.06
Efficiency, including grate, per cent.	68.3	71.5

Saving of coal $\frac{71.5 - 6.83}{.683} = 4.7\%$

That the power plant operators of Canada recognize the value of mechanical soot blowers is evident from their large volume of purchases of this equipment.

COMBUSTION CHAMBER

The space back of the bridge wall in the ordinary horizontal tubular boiler, and any space that may be equivalent to it in boilers of other types, is known as the "combustion chamber." The gases from the fuel-bed, and any supplementary air that may have been admitted at the fire doors or elsewhere, should have become thoroughly mixed by the time they have passed the bridge wall; but the chemical combinations that begin at the fuel-bed are still incomplete, as a rule. The combustion chamber is in effect a local enlargement of the general channel followed by the hot gases, and it serves to temporarily check their velocity and afford time for the completion of the oxidation. To accomplish this end properly, the combustion chamber should be ample in size, and it should be kept well cleaned out. Otherwise the fine particles of coal and ash that lodge in it will collect until the entire space becomes nearly choked up. A combustion chamber thus neglected fails to fulfil its mission, because it does not prevent the gases from passing swiftly onward to the tubes, and becoming thereby chilled, by intimate contact with the relatively cool surfaces of the boiler, so that further combination does not occur.

Transformer Connections for Power Transmission

The Various Types of Transformer Connections in Common Use Are Described and the Electrical Characteristics of the Resulting Circuits Are Gone Into Fully—A Number of Connections Are Described Which Are Not in General Use

By GORDON KRIBS

THE development of the modern alternating current transformer dates from twenty-five years ago, when it was just emerging from the experimental stage. It was the invention of the alternating current transformer which made possible the use of the alternating current system of long distance power transmission. True, a few long-distance direct-current systems have been installed under the Thury patents, but they have not been a practical success. Previous to the invention and application of transformers to alternating current work, all electrical distribution was direct current. The main advantage of alternating as compared with direct current transmission and distribution is due to the ease with which electrical power can be transformed from one voltage to another, which alone makes long distance transmission of electric power economically possible.

The purpose of this article is to describe a few of the more common methods of connecting up single-phase transformers to the various systems of electrical distribution to produce the desired results under definite given conditions.

In order to fully understand such matters it is necessary to review the properties of single, two and three-phase currents.

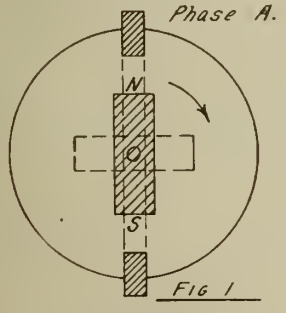


FIG. 1—ELEMENTARY SINGLE PHASE MACHINE

Fig. 1 represents a single-phase machine with a single armature coil. The field consists of a permanent magnet with a north and south pole. The current generated in such an elementary machine is alternating, the frequency depending on the speed. It is apparent that to generate one complete cycle the field has to turn through a complete circle, which is equivalent to 360 degrees. The maximum voltage in the armature coil occurs when the field is in the position shown full. When the field is in the dotted position the voltage wave is passing through zero, and when the field is again in the full position with the poles reversed the voltage wave is again maximum in the negative direction.

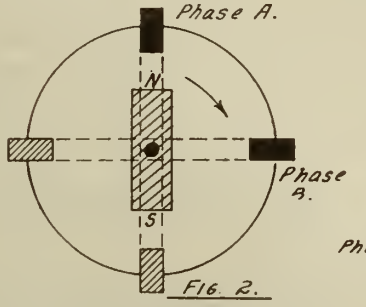

FIG. 2—ELEMENTARY TWO PHASE MACHINE.

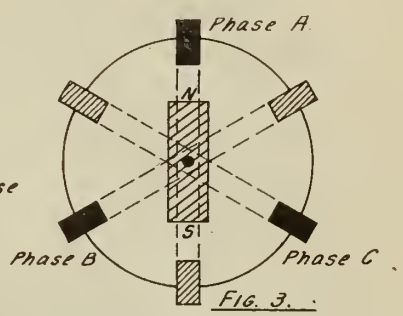

FIG. 3—ELEMENTARY THREE PHASE MACHINE.

Fig. 2 represents an elementary two-phase alternator with one coil only in each phase, the revolving field consisting of a permanent magnet with a north and south pole. The current generated in each of the coils is alternating, the frequency depending on the speed. To generate a complete cycle in each of the coils or phases, the field must revolve through 360 degrees or a complete circle. The maximum voltage occurs in phase A when the field is in the position shown. In order that the voltage in phase B may reach a maximum the field has to turn through ¼ circle or 90 degrees. It is thus apparent that in a two-phase circuit the one-voltage wave is 90 electrical degrees ahead of the other and hence a two-phase circuit is sometimes called quarter phase.

Fig. 3 represents an elementary three-phase machine with one coil only in each phase and a single permanent magnet field as before. It will be seen that the field must travel 120 degrees, or one-third of a circle from position of positive maximum voltage in phase A to position of positive maximum voltage in phase B and similarly for phase C, so that it is readily seen that the voltage waves in a three-phase circuit are 120 electrical degrees apart.

Description of Transformer

The constant potential transformer consists essentially of one or more primary coils and one or more secondary coils wound on an iron core and carefully insulated from each other and the core. It is usually assembled in some form of outer protecting case and the intervening space filled with insulating fluid such as oil, which acts not only as an insulator but also as a means of carrying the heat generated within the transformer to the casing and thence to the outer air. If the primary winding of a transformer were connected to a direct current source of power of the proper voltage it would constitute a short circuit. On account, however, of the systematically changing value of alternating currents, the magnetic flux produced in the iron core generates a voltage in the primary winding which is opposed to the incoming or line voltage. This counter voltage holds the current down to normal value which, neglecting losses, is just sufficient to produce a voltage in the primary coil equal and opposite to the incoming voltage. If a current flows in the secondary it is opposite in direction at any instant to that in the primary coil and tends to neutralize the flux generated by the primary and hence lowers the counter voltage and this automatically allows more current to flow in the primary as the load in the secondary increases.

Since, ignoring leakage, the same magnetic flux passes through both primary and secondary coils it is apparent that the ratio of the primary to the secondary voltage of the transformer is the same as the ratio of the number of turns in the primary to the number of turns in the secondary. Thus, if the primary has 2,000 turns and the secondary 200, the ratio of turns is 10 to 1 and the ratio of primary to secondary voltage will be 10 to 1, viz., if the primary voltage is 2,200 volts, the secondary voltage would be 220 volts.

Vector Diagrams

Many problems involving relations resulting from various transformer connections can be readily solved by means of vector diagrams. Take the case of the single-phase transformer, Fig. 4.

The primary coil is connected across the mains, having a voltage of 2,000 volts, and the voltage across the secondary A to C is 200 volts, i.e., the ratio with the two secondary coils in series

is ten to one. It should be noted that at any particular instant the currents in the primary and secondary coils flow in opposite directions and that the volt-

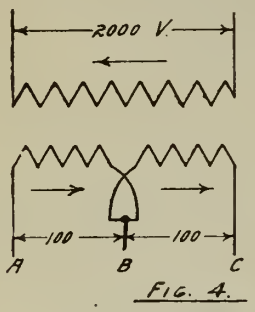

FIG. 4—SINGLE PHASE TRANSFORMER.

ages in all coils of the transformer are in phase, i.e., reach maximum and minimum values at the same instant.

Any voltage may be represented by a straight line of a certain length according to the scale used. Thus, in the above example a line 1 in. long may represent the voltage A B=100 volts. If we wish to add the voltage B C, which is in phase with A B, it is merely necessary to draw another line 1 in. long from the end of the first one and in line with it, the total length being 2 in., and on the basis of our assumed scale representing 200 volts.

In the case of a two-phase transformer combination as shown in accompanying sketch, Fig. 5, we have two transformers

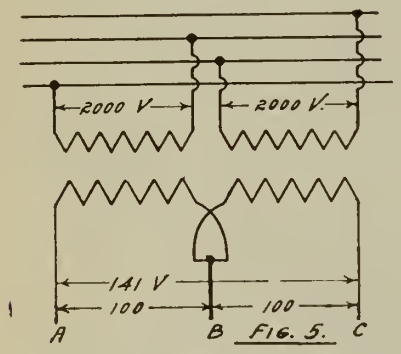

FIG. 5—TWO PHASE TRANSFORMER CONNECTION.

connected to a four-wire two-phase system with their secondaries connected for three-wire, two-phase, wire B acting as a common return for both phases.

As pointed out previously the voltage waves are 90 degrees out of phase with each other. To represent the voltage relations by means of vectors,

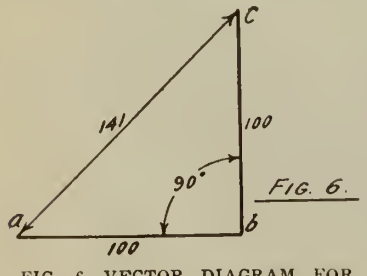

FIG. 6—VECTOR DIAGRAM FOR TWO PHASE CONNECTION.

draw line a b, Fig. 6, of such length as to represent 100 volts, and from 6, draw b c, at 90 degrees to a b, to represent 100 volts at 90 degrees phase relation with a b. Now the distance a c to the same scale represents the voltage between the two outer wires, which, when scaled off, is found to be 141 volts in-

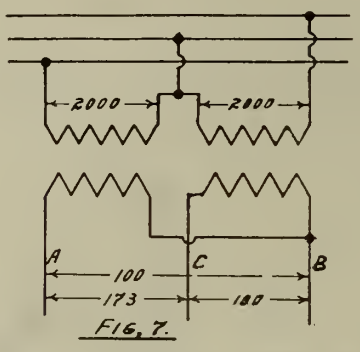

FIG. 7—THREE PHASE TRANSFORMER CONNECTION.

stead of 200 as in previous example. It should be noted that 141 volts is the equivalent of 100 volts $\times \sqrt{2}$, in other words the sum of the two equal voltages in a two-phase circuit equals either voltage multiplied by $\sqrt{2}$, to 1.41.

In the case of a three-phase transformer combination we will assume that we have a transformer connection similar to that shown in Fig. 7.

As pointed out previously the voltage waves of a three-phase alternating circuit are 120 degrees out of phase with each other. If we draw a line a b (Fig. 8) one inch long to represent the voltage

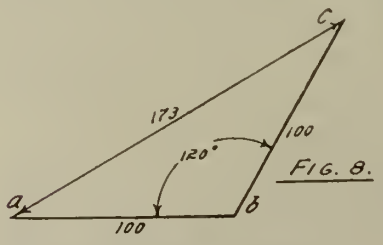

FIG. 8—VECTOR DIAGRAM FOR THREE-PHASE CONNECTION

A B = 100 volts, then the voltage B C may be represented by the line b c, which is one inch long and makes an angle of 120 degrees with a b. The distance a c will represent the difference in voltage between the lines A and C, which in this case is 173 volts. It should be noted that 173 volts is the equivalent of 100 volts $\times \sqrt{3}$.

SYSTEMS OF TRANSFORMER CONNECTIONS

For the purpose of making a preliminary study of transformer connections, the various systems may be divided into the following groups:

(A) Single-phase connections.
(B) Two-phase connections.
(C) Three-phase connections.
(D) Two-phase—three-phase connections.

We will consider them in the order named.

(A) Single-Phase Connections

The ordinary single-phase transformer such as is used on distributing systems consists of two circular primary coils and two similar secondary coils.

The primary coils are ordinarily connected in series for 2,200 volts, while the secondary coils have all their terminals brought out and can be arranged either in series or parallel. Sometimes the high-tension coils are arranged with reduced voltage taps so as to take care of poor line regulation.

In Fig. 9 we have a standard lighting transformer with its secondaries connected in parallel for a 110-volt 2-wire light-

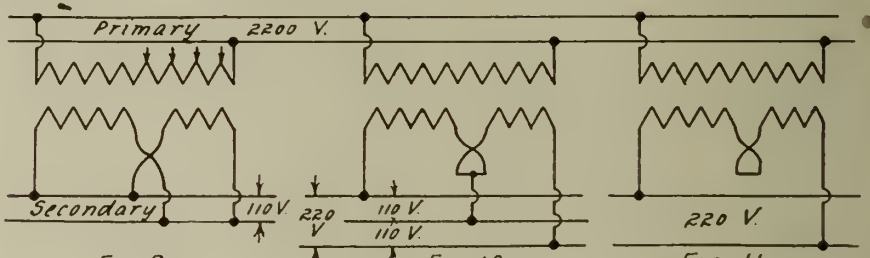

FIG. 9 110 VOLT, 2 WIRE CONNECTION.

FIG. 10—THREE WIRE, 220 110 VOLT CONNECTION

FIG. 11—220 VOLT CONNECTION

ing main. The two secondary leads in the centre are ordinarily crossed before bringing them out of the case as shown in the diagram. Reduced voltage taps are shown on the high-tension winding.

In Fig. 10 we have a standard lighting transformer with secondaries connected in series with a tap taken off the middle or neutral point for 110-volt-220-volt, 3-wire lighting mains.

In Fig. 11 the secondaries are shown connected in series for 220 volt power service.

Transformers may also be connected in parallel with their secondaries supplying the same set of secondary mains. Care should be taken in connecting transformers in parallel to see that the polarity of the transformers is the same. One transformer might have either its secondary or primary winding wound in the opposite direction with respect to the other, in which case corresponding leads of the secondary would be opposite polarity, and if connected in this manner would produce a short circuit. Interchanging leads on one side or reversing the order of bringing the leads out of

the case will also reverse the polarity. In connecting a transformer in parallel with another already in circuit, one side of the secondary should be fused lightly before the primary plugs are inserted in order to protect the transformer from damage in case the potential is reversed.

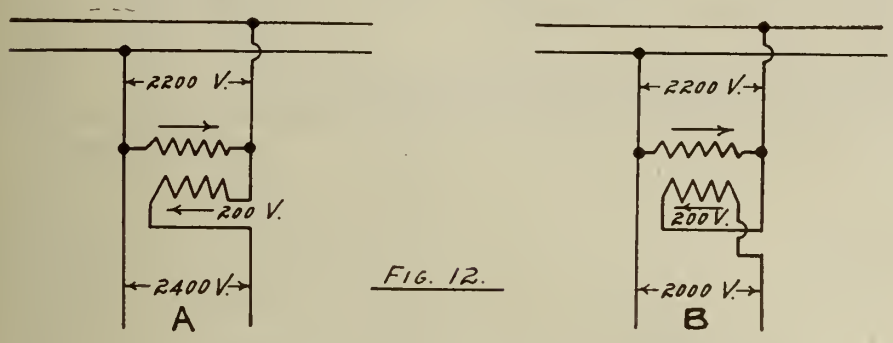

FIG. 12—METHOD OF RAISING OR LOWERING VOLTAGE.

If the fuse does not blow, the secondary may be connected in permanently. Some companies make it a practice of fusing the secondary of all transformers in parallel. Transformers in parallel are particularly subject to burn-out, since if one transformer during a period of heavy load becomes damaged and the fuses blow from this or any other cause, it throws an additional load on the other transformers in circuit with it and they will probably burn out one after another.

Sometimes it is found that the primary voltage on a certain line is too low, and that it is advisable to increase it, or possibly it is too high and it is desirable to lower it. This may be done by means of a boosting transformer, which is merely an ordinary lighting transformer connected in as shown in the following diagrams:

In Fig. 12A, an ordinary lighting transformer is connected in circuit so as to increase the voltage in this branch main from 2.200 to 2,400 volts.

In Fig. 12B the transformer is connected to buck the primary voltage and the voltage in the branch main is thereby reduced from 2,200 to 2,000 volts. Transformers arranged for either bucking or boosting should be connected in solid and without fuses—otherwise abnormal voltages will be produced in the transformer in case a fuse blows. Care should be taken to select a transformer for this purpose whose secondary has sufficient current-carrying capacity to carry all the current flowing in the main. Thus, in either of the above examples if 100 amperes is flowing in the main, a 20 kw. transformer would be needed for a booster.

(B) Two-Phase Connections

As pointed out previously a two-phase circuit is simply two single-phase circuits in which there is a fixed phase relation between both the voltage waves and current waves of 90 electrical degrees. Ordinarily two-phase power is transmitted over four wires—there being no electrical connection between phases either primary or secondary.

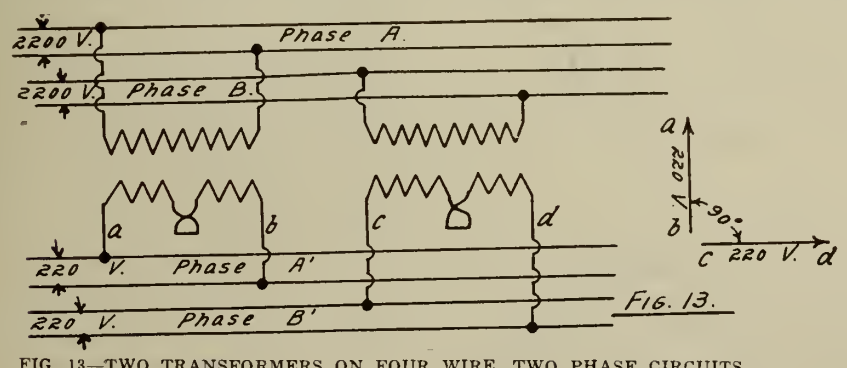

FIG. 13—TWO TRANSFORMERS ON FOUR WIRE, TWO PHASE CIRCUITS.

In the diagram, Fig. 13, we have the ordinary method of connecting two transformers on to two-phase circuit.

Sometimes, however, the two central wires of a two-phase system are combined into one which is common for both phases and carries 141 per cent. as much current as the other two wires. In this case the transformer connections are as shown in Fig. 14.

It should be noted that the voltage between the two outer wires of the primary is in this case 3,120 volts instead of 2,200, also that the voltage across the two outer wires of the secondary is 312 volts. This is readily seen by reference to the vector diagram. By taking a tap off the middle point of either transformer 110 volts for lighting purposes can be obtained between this tap and either of the other leads of the transformer. The voltage difference between X and Y is 156 volts. Thus four different voltages may be secured from this combination viz., 110, 156, 220, 312 volts. It would be necessary, however, to have a 5-wire secondary to make these various voltages available.

(C) Three-Phase Transformer Connections

A three-phase power circuit is a combination of three single-phase circuits so arranged that the voltage and current waves in each circuit have a definite phase relation of 120 electrical degrees with either of the other two. Ordinarily three wires are used to conduct these three single-phase currents, each wire acting in turn as a return circuit for the other two. Sometimes, however, a fourth or neutral wire is used under circumstances such as will be explained later.

The most common methods of connecting transformers in three-phase systems may be enumerated as follows:

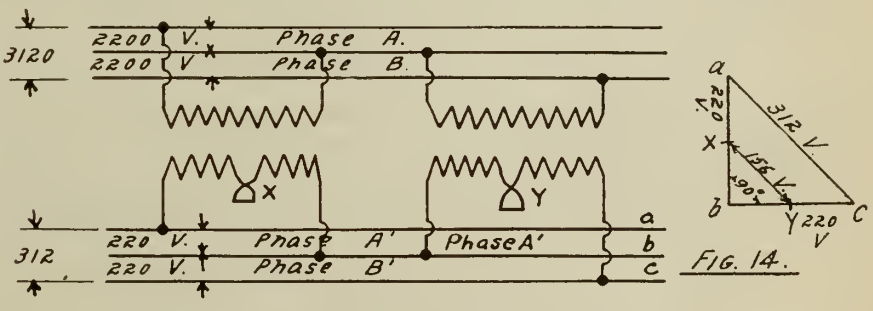

FIG. 14—TWO PHASE, THREE WIRE CONNECTION.

1. Delta to Delta.
2. Delta—Star (Y to Y).
3. Delta to Star.
4. Star to Delta.
5. Open Delta.
6. T connection.
7. Open Y—Open Delta.
8. Three-phase Booster connections.

1. Delta to Delta Connection

In the Delta-Delta connection three transformers are used and the system is so called from its supposed resemblance to the Greek letter D, or Delta.

All three transformers are connected in series, the end of one coil is connected to the beginning of the next, making the circuit complete with three junction points, one live wire being attached to each of these points, as in the accompanying diagram, Fig. 15.

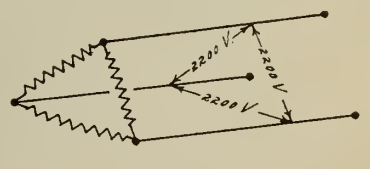

FIG. 15—DELTA CONNECTION.

In the Delta-Delta connection, both primary and secondary are connected in this manner.

An example of a three-phase Delta-Delta connection is given in Fig. 16. In this case we have a three-phase, 2,200-volt line, and desire to secure a three-phase 220-volt power circuit and one 110-volt lighting circuit.

It should be noted that the three transformer coils connected in the Delta form a closed circuit by themselves and that the line wires are attached to these points.

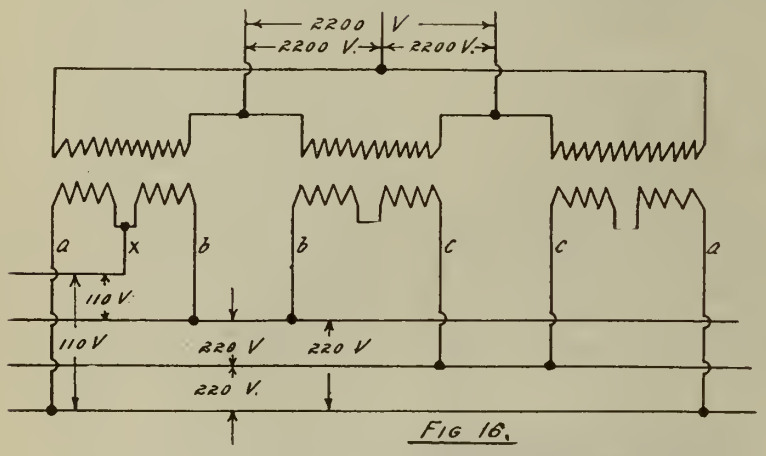

FIG. 16—THREE-PHASE DELTA-DELTA CONNECTION.

In order to fully understand the conditions existing in the secondary of a bank of transformers connected as in the above diagram, it is well to draw a vector diagram. Proceed as follows:

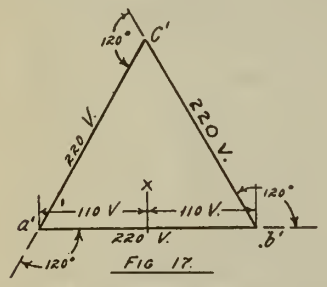

FIG. 17—VECTOR DIAGRAM FOR DELTA CONNECTION.

Draw a' b', Fig. 17, to such a scale that it represents 220 volts, i.e., the voltage across the transformer terminals a-b. The voltage b' c', is also 220 volts and can be represented by the same length of line, but there is 120 degrees phase difference between 'a b' and b' c'. Hence mark off an angle at b' equal to 120 degrees, and draw b' c' equal to 220 volts. Similarly c' a' represents the voltage across the terminals c-a. The completed diagram represents the line voltages in magnitude and phase—the line voltage and the transformer voltage being identical in the Delta connection and hence the primary voltage of the transformers must be the same as that of the incoming line. The current-carrying capacity of the transformers however, need be only 58 per cent. of that of the incoming line, or in other words the current in the line is 1.73 times that in the windings of any one of the transformers in a Delta group. This may be explained as follows:

In a Delta-connected bank of transformers we have two transformers in parallel, taking current from or giving current out over one line. These currents, like the voltages, are not in phase with one another, but are 120 degrees out of phase, hence they cannot be added numerically, but must be added vectorally as in Fig. 18. It is thus seen that if we have two transformers of a delta group each supplying 100 amperes to the same line, the line current will not be 200 amperes, but only 173 amperes, or 1.73 times the current in each transformer, and the current in each transformer winding will be 100 amperes, so that the current in each transformer will

$$\frac{100}{173}$$

be ——, or 58 per cent. that of the line current.

It should also be noted that at unity power factor the line current is out of phase with the transformer current by 30 degrees. The transformer current and transformer voltage, however, are in phase at unity power factor.

In the case of Delta-connected transformers, if one transformer is burned out or otherwise disabled, it is quite possible to continue to supply three-phase service after the disabled transformer is cut out, although the capacity of the bank will have been reduced to 58 per cent. of its capacity with three transformers. This will be further explained under the V or Open-Delta connections.

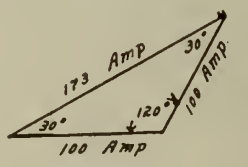

FIG. 18—CURRENT VECTOR DIAGRAM FOR DELTA CONNECTION.

(To be Continued)

BANKING FIRES

When the boilers are to be put out of service for a short time, but are nevertheless to be kept hot and ready to be restored to use within a few hours, it is customary to "bank" the fires instead of drawing them or allowing them to burn out. The operation of "banking" consists in disposing of the fires so that they will cease to burn actively, the combustion being reduced to the lowest limit that is compatible with the maintenance of the ignition. In this way unnecessary and wasteful loss of fuel is avoided, while at the same time a large body of intensely hot coal is maintained in a condition that makes it possible to start up the fire again very easily, and with little loss of time or material.

Fires that are to be banked should first be well cleaned, and a supply of fresh coal should be thrown upon the grates and allowed to become well ignited. The dampers should next be nearly closed, and the fires pushed back against the bridge wall so as to leave the front part of the grates bare. The fires should then be entirely covered with a considerable supply of fresh coal, the front part of the grates being still left bare, however, so that any air that enters the ash-pit may pass up into the furnace freely, and over the deadened fire instead of through it. Some firemen haul the fire forward, and bank it in a windrow across the front of the furnace. It will keep best if covered with fine, damp coal, well tamped down; for a crust then forms over it which excludes the air so effectively that the fire will often remain alive for two or three days.

Coal-gas is slowly distilled off from a banked fire, and to guard against accident from the ignition of explosive mixtures of gas and air in the furnace and the passages connected with it, care should be taken to ensure sufficient ventilation of the furnace and its connections by permitting a small quantity of air to stream continuously up through these spaces and out into the stack. The ash-pit doors should be closed tightly, and the damper in the uptake of the boiler should be as nearly closed as is compatible with the maintenance of the ventilation to which we have just referred. To guard against the accumulation of explosive gas mixtures, dampers are usually perforated so that they will pass a small amount of air even when they are set squarely across the uptake, and when such a perforation exists it will usually afford sufficient protection against gas explosions, provided a circulation through the furnace is made possible by admitting a slight amount of air above the grates. The fire doors should be opened by a mere crack, if the furnace is of the usual type; but if it is built with a hollow bridge wall as previously explained the air needed for ventilating the setting may be admitted by way of the bridge wall openings.

Our Question Box

What is Heat? Heat is a form of energy. By touching a body we can tell whether it is warmer or colder than the hand and by touching two such bodies in quick succession we can form a rough opinion as to their difference in hotness or coldness over a limited range, the colder body, if of the same material and of the same size, will contain less heat than the hot body or less energy is stored up in it in the form of heat. From physical reasoning it is possible to conceive of a body which has no heat at all and this body will have a temperature of absolute zero. This point has never been reached by experimental methods but has been approached to within a few degrees.

What is Cold? Cold is merely the absence of heat and in the usual sense it is used in comparing one body with a hotter one.

How is Heat Measured? By means of a thermometer which measures the temperature of the body and by means of its specific heat or the amount of heat which it contains. The amount of heat in a body depends upon its temperature and upon the material of which it is composed as well as upon its mass. Some materials require a greater amount of heat to raise them through one degree of temperature than others, for instance water requires about eight times as much heat to raise it through one degree as cast iron for equal weights.

How Was the Thermometer Discovered? The thermometer was discovered by Galileo, who first developed a thermometer having a tube with a bulb at the top. The tube dipped into a colored liquid. Temperatures were indicated by the expansion or contraction of the air in the tube and bulb, which caused the liquid to be drawn up or forced out the tube. While sensitive this thermometer wasn't very satisfactory for it was subject to fluctuations according to barometric pressure. The more modern form of thermometer with a bulb, a sealed tube and a contained liquid is also attributed to Galileo, about 1612.

Alcohol was the first liquid used and the graduations employed on the Fahrenheit thermometer were proposed by Gabriel Daniel Fahrenheit in 1714. He proposed to take as zero the lowest temperature obtainable by a mixture of ice and salt and to divide the space between this point and that of the temperature of the human body into 96 degrees. The fixed points were afterwards chosen at that of melting ice and that of boiling water at standard atmospheric pressure. This with the old divisions retained gave 32 deg. for melting ice and 212 deg. for boiling water.

For general scientific purposes the centigrade system is usually adopted. This has the zero freezing point marked zero, and the boiling point 100 deg., giving 100 degrees in between. The absolute zero spoken of above is 273 deg. Centigrade below the Centigrade zero.

How are the Fahrenheit and Centigrade Scales Converted from the One to the Other? Nine Fahrenheit degrees equal five centigrade degrees and this gives us a means of converting from one to the other. One other thing must be remembered and that is the difference in the marking of the freezing points, Centigrade, 0 deg., and Fahrenheit, 32 deg. To transform Centigrade to Fahrenheit then multiply by nine, divide by five and add 32 deg. To transform Fahrenheit to Centigrade, first subtract 32 deg., then mutiply by five and divide by nine.

If a Fahrenheit Thermometer Gives the Temperature of a Bearing as 62 deg., What Temperature would be a Centigrade Thermometer Read? Subtract 32 deg., multiply by five and divide by nine. The result will be 17 deg. (nearly).

What is Meant by a British Thermal Unit (B.T.U.)? A British Thermal Unit is the amount required to raise the temperature of one pound of water through one degree Fahrenheit from a temperature of 60 deg. Fah. The temperature from which the water is to be raised is specified because the amount of heat necessary to raise the water through one degree varies slightly with different temperatures. What is it a measure of? It is a measure of the quantity of heat.

How Many B.T.U.'S are there in a Pound of Good Coal? Good coal runs from 13,000 up to 14,500 B.T.U. per lb. These figures are of course only approximate and coal varies greatly in its calorific value.

What is the Mechanical Equivalent of Heat? The mechanical equivalent of heat is the number of foot-pounds of mechanical energy equivalent to one British Thermal Unit. The most probable value is probably 778 foot-pounds to one B.T.U.

If all the Heat in One Pound of Coal Could be Turned into Horsepower, How Many Horsepower Hours Would be Produced? One heat unit or one B.T.U. equals 778 ft. lbs. Assuming a value of 14,000 B.T.U. for one pound of coal the number of foot lbs. of work stored in it will be $14{,}000 \times 778$. One horsepower hour equals $33{,}000 \times 60$ foot lbs. Therefore the number of horsepower hours will be $14{,}000 \times 778 \div 33{,}000 \div 60 =$ 5.4 h.p. hours.

DAMPERS

The damper in the flue leading to the chimney or stack is intended for regulating the fire, and thereby controlling the steam pressure also. It is much better to check the draft by closing the damper partly or wholly, rather than by opening the fire doors so as to admit cold air into the furnace. The damper should be nearly closed when firing or cleaning fires, to prevent chilling the boiler by the large quantity of cold air that would otherwise be drawn into the furnace. Just enough draft should be left on, at these times, to prevent flames or hot gases from rushing out through the fire doors when they are opened. Automatic regulators are now common, for closing the dampers when the steam pressure exceeds some predetermined value. They are actuated by the pressure of the steam against a piston or a flexible metallic diaphragm. In heating residences by steam, automatic damper regulators (usually of the diaphragm type in this case) are almost a necessity; because if they were not employed it would be necessary to have an attendant nearby during the entire day.

LEAKAGE THROUGH BRICKWORK

Care should be taken to keep the joints of all the brickwork about the boiler tight, so that air cannot leak in through any part of the setting, and mingle with the products of combustion. Leakage of this kind chills the furnace gases so that the heat is not absorbed from them with the same readiness, and it also injures the draft. The action of the air that leaks in through the setting is similar, in these respects, to that of the air that enters through the fire doors when they are left open too far. It is not necessary that the openings admitting the air through the setting should be individually large, in order to experience undesirable effects, for the multitude of small chinks that exist in a loosely-built brick wall can unitedly pass a very considerable quantity of air. Leakage directly through the brickwork of boiler settings is much more common than might be supposed, and in many cases there is a serious loss of economy from this cause, which is not detected because its existence is not realized. These considerations show the importance of keeping the brickwork of the setting in good repair at all times.

Canada's Power Developments

A PRELIMINARY announcement issued by the Commission of Conservation appears on another page of this issue and furnishes interesting information concerning the state of Canada's power development. This report is preliminary to a complete report shortly to be issued by the Commission and shows the importance of water powers in our industrial life.

As might be expected, steam power is used to a greater extent where supplies of native coal are available, as in the Maritime and the Prairie Provinces, while in British Columbia water and coal are both abundant. The most interesting suggestion brought forth is that for the Prairie Provinces, where it is suggested that it would be most economical to generate electric power in large central steam plants and to distribute it over transmission lines.

This suggestion is almost identical with the power centralization scheme now being worked out for England and the economies which will be effected in England could be duplicated here with little effort in some parts of the country where conditions are especially favorable. This use of the Western lignites would make the high tension transmission line as familiar in the West as it is in the Niagara district. The figures, Province by Province, are especially interesting and show how greatly power development is influenced by manufacturing industries. Ontario is well in the lead with a total plant capacity of 899,856 h.p., with Quebec coming next with 625,061 h.p.

The highest head in Eastern Canada is 540 feet at the 8,000 h.p. plant at Eugenia Falls, Ont., while in the West, a head of 1,820 feet is utilized at Britannia Beach, B.C. The total horsepower developed in Canada is shown to be well over 2,000,000.

An Oliver Message of Optimism

THERE'S something in the attitude of the Oliver Machinery Co. of Grand Rapids, Mich., that is well worth noting just now. They state that business has been good with them and they are not afraid to stand up and say so.

Why not others? We have had a regular procession of reports about cancellations of contracts and the subsequent difficulty of readjustment. We have been getting yards of material about firms "waiting" to see if there is going to be any change in the price of raw material. But there are few—mighty few—who are coming right out into the open and owning up to the fact that business is good enough to earn them three meals a day.

Here is what the Oliver people have to say about it:

"The month of January, 1919, showed the biggest shipment the Oliver Machinery Company has made in their history. Part of this is due, without question, to the fact that our export business has replaced some of the domestic business of previous months. Old export orders were allowed to be filled because of shipping conditions improving.

"Orders received during the month of January were also very gratifying, being within 10 per cent. of our average monthly business for the past year, while a part of our business, and we might say a substantial part, is export. At the same time, every time we receive an order for a carload of machinery for export we must bear in mind that we have to purchase a certain amount of steel, which purchase is domestic business. We have to purchase almost a carload of cast iron, which is indeed domestic business, etc., until all of the parts that go into our machinery are ordered. We hope that other people who are actually enjoying a good volume of business will publish the fact in the hope that those who are putting off purchases unnecessarily will see the error of their ways."

That message ought to be passed on. There's nothing so bad for the dumps as to find out that some person else has 'em. There's nothing that will help along a feeling of doubt and pessimism like a sermon from a man who is a regular honest-to-goodness pessimist himself. And there's nothing that will cure this thing so effectually as a good dose of "business is good" talk from men who are honest enough to say so.

All You Could Have Done Was Kill Us

Meester Editor:—

Some time ago I tol you about dat inspector not letting me run ze power machines because I could not answer some question. Well, I go back and tell ze Boss I better tak ze job cleaning everything and ze boilers, and for hem to get some ozzer feller with a cer-tif-i-cat. Ze Boss say "sure"—your pay will now drop to eight bucks ze week. Sack-ree, zat only pay for my board. Well, I mak up my mind I read and learn. One day ze Boss come along when I am sit and read and learn about not waste exhaust steam, and ozzer zings. He say, Batistee, what ze blazes you do for a living? I say, nozzong Boss. Ha he say, by gar I zink so to. Better do something if you want to stay around here. Just den, bang, roar, goes ze steam from ze safety valve. I say, Boss, I just am reading about dat exhaust steam, every clowd wasted is a big dollar bill los, why not hitch ze feed water heater to ze safety valve. He say, by gar, if dat new feller got cer-tif-i-cat it must be to waste steam. Just den, zip, plunk, plunk, ziss, ziss, go ze blow down, dat cer-tif-i-cat feller had let ze water get to high in ze boiler. I say Boss, I just been reading about wasting hot water, every few gallons trew away means more dollar bills gone, better hitch dat blow down pipe to ze baths. Sacre-dam, said he, what dat certif-i-cat feller means anyhow. Just den, fizz, fizz, fizz, goes de blow down pipe on one of ze boiler skimmers. De Boss jump in ze air and say a lot of cuss words. Be hevins, said he, is the devil trying to blow ze insides all out of ze boilers. I zink ze Boss is Irish. I say Boss, I just been reading about dose skimmer zings, every time dey is blown down when zey should not, dere is a waste of steam. He yell, the Lord help me to kill dat cer-tif-i-cat feller. Just den ze whistle start to shriek for ze quit at noon. I say, Boss, I just been reading zat during dese times ze whistle she should be only blow about half as long as before. Zen ze Boss yell, blast you Batistee, you and your reading, why did you not have dat cer-tif-i-cat. All you could have done was kill us, ze other feller will ruin us, which is a lot worse. Boss, I say, I just been reading zat ze Boss should never get mad before his men, he loze his dignity and zay laugh at him. He yell, Batistee, if you tell me any more about what you have just been reading, I will poke your eyes out wit a crowbar. Where do you get all dat reading anyhow. I say in ze Power House. I soon be able to got dat cer-tif-i-cat my own self. He say, lend me dat book I will show it to ze feller what knows all about wasting steam and water and coal. I gess zat feller got his cer-tif-i-cat when ze law came in force, he sure never was examined. I say, sure, dat is right, but next year some fellers will drop hard if zey are not lak me and start to read and learn. I was only joke when I say to hitch doze safety valve to ze heater and ze other pipe to ze baths. Ze book say it mighty bad to let water get too high in ze boilers, when ze engine run she might go bang on zee cylinder head, and it be better to flow down at ze lowest pressure carried and when ze load is smallest. It say ze skimmers should be blow according to ze dirt in de water used and lots of oder tings lik dat, I tell you Boss, I get zat job back pretty soon when I am a real engineer wid a real engineer's cer-tif-i-cat.

—Batistee Sefor

A LESSON IN THRIFT

A colored gentleman went into a down-town store to buy a suit of clothes. He wanted to pay about $20. In fact he had that much set aside for the purpose.

The clerk, well schooled in the art of making people buy what they couldn't afford to pay for, got the customer prancing around in a $35 outfit, and was telling him that that was the sort of togs he should wear.

The colored man simply smiled, stuck out for a $20 outfit, and remarked: "I never hang my hat no higher than I can reach."

And there's quite a heap of common sense and wisdom in the saying.

Is there anything more painful than witnessing a man with a $2,000 income trying to make a splash that looks like that of his neighbor who reaches through the cashier's wicket for $5,000 per annum?

And yet it's being done all the time. Two dollars can't go as far as five, and two thousand can't do what five thousand can. That looks simple enough, but the people who fail to realize that fact would make quite a heap were they all pitchforked up together.

That colored man preached a pretty fair sermon on "thrift" when he announced his text as "I never hang my hat no higher than I can reach."

Association and Personal

ALBERTA C.A.S.E.

EDITOR, POWER HOUSE: If I can beg sufficient space I wish to show readers of this valuable magazine what The Canadian Association of Stationary Engineers are doing in Alberta.

Several of the most progressive engineers in this district realized the need of a more co-operative feeling among the engineers, so we got together last June and applied for a charter. We have had a hard fight but we have all pulled together and we now have as good an organization as there is to be found in the West.

Our first benefit to the engineer is the indicator. With this we are able to find our engine and piping faults and thus greatly increase the efficiency of the plant and smooth out its operation to the benefit of our employers and ourselves, thus increasing the value of our services. We own an indicator of the best make with a cylinder and piston for ammonia and high and low pressure. Each member has it one week at a time and is instructed in its benefits.

Our service cards are of great value to the employer and the engineer. Each member's experience, education and qualifications are listed and a complete record of him is kept. When he applies for a position our secretary mails this record and references, which we are back of, to the prospective employer. Also, when employers enquire for engineers, these records prove their worth. Since our whole object is to raise the standard of engineers, this is a great incentive to the engineer to try and raise his own standard.

The grading of engineers according to their experience and qualifications is another of our strong points. Since Alberta has a high standard in this line for steam engineers, our efforts are not needed, so we turn our attention to the electrical worker, and steam engineers wishing recognition along this line. We have an examining board, and grant certificates in four grades to those having the required experience and satisfactorily passing the examinations for the respective grades. The requirements are such that any engineer holding our certificates will be able to prove to the public his worth, so that when employers become acquainted with us they will know the value of a member of our organization.

We have received hearty support from the employers here and leading engineers, and the Alberta Government have shown themselves on our side, so we feel that our work is not in vain. It is our ambition, now that the war is over, to keep the engineers up to the high efficiency they tried so hard to maintain during the war. We wish every engineer to wake up and co-operate with us and try to raise his standard of thinking and working and thus help to raise the standard of all.

We are not a union, nor in any way connected with them in the general term union goes. However, we recognize the necessity of such, and know that union is strength, but we also know that strength is not of much value without the guiding hand of intelligence. Trade unionism progresses by strikes and intimidation. The C.A.S.E. never countenances coercive measures to secure justice for engineers. The trade union adopts standard wages regardless of a man's efficiency, but this policy can never be in harmony with the principle of engineering, where individuality and individual ability must always be recognized.

In order to obtain its objects, the C.A.S.E. believes in individual salesmanship of personal services more than collective bargaining, in demonstration of worth rather than demands with threats, in pay according to economic value rather than a pyramiding scale of standard wages, in publicity regarding working conditions that are unsatisfactory rather than methods of force.

We do not mean by this that we are against unionism. We know that with intelligent guidance it has its place and value to the laboring classes, and is often the only means of getting justice for the under man. We are not against the union engineer, we are here to help him and wish him to help us, to come in with us and let us all stand for safety, reliability, economy, and intelligence, and a square and honest deal to employer as well as engineer.

H. E. WIGHT.

TORONTO SECTION A.I.E.E. HOLD INTERESTING MEETING

The manufacture of electrical porcelain was dealt with in a paper read before the Toronto section of the American Institute of Electrical Engineers on Jan. 7, by Hugo J. Lundgren, of Peterborough. Both the wet and dry processes of manufacturing porcelain were described and the various operations were shown by means of slides.

Elements for suspension insulators and similar parts required in quantity are molded in steel dies in a press with special precautions to prevent the clay sticking to the mold. A few years ago a record was achieved by an insulator which took a puncture test of 15,000 volts, the insulator being one of the same size and shape as that used on telegraph lines. To-day, twenty-five years later, with the same raw materials a porcelain is made which will stand a test of 15,000 volts per millimetre. Above seven mm. the dielectric strength becomes less. A greater proportion of feldspar will increase the dielectric stress, but usually at the expense of the physical properties. Under ideal loading conditions the compressive strength might be taken at 8,000 lbs. per sq. in. and the tensile strength 24,000 lbs. per sq. in. in practice.

Canada's raw materials for the manufacture of porcelain are not abundant, and at the present time the kaolin and other materials are imported with the exception of feldspar, of which unlimited quantities are available.

GET THE RIGHT QUANTITY OF AIR

To obtain ideal results, the total quantity of air admitted to the furnace, including that which passes up through the fuel and that which enters at the fire doors or through other openings, should be exactly adjusted to the needs of the fire. The admission of an excess of cold air is wasteful, because this excess serves no useful purpose, and yet it becomes heated in passing through the furnace. The heat that is required to raise this excess air up to the temperature that prevails in the uptake, where the gases leave the boiler to pass to the stack, is entirely wasted. This source of loss is real, and it should be remembered and considered; but as it is practically impossible to admit exactly the right amount of air to the furnace, and to admit it in precisely the right manner, it is exceedingly important to note that it is far better to admit too much air than too little. This is because the loss of heat by the distillation of unburned substances from the coal, and by the escape of the carbon monoxide gas that is usually present in large quantities when the air supply is deficient, is far greater than any loss that is likely to arise from the admission of an excess of air, when the fireman is careful and intelligent.

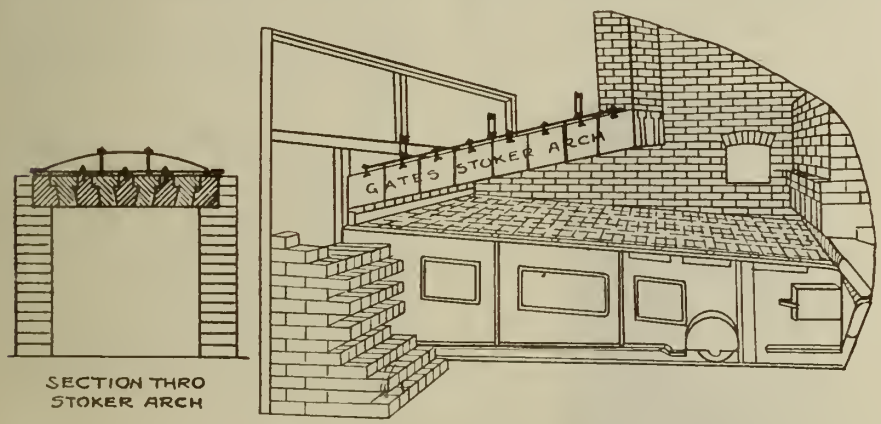
Progress in New Equipment

NEW SUSPENDED AND SELF-SUPPORTING ARCH

THE greatest source of expense in connection with the operation of furnaces, is the destruction of the brick lining in the fire chamber. In many instances it is necessary to dismantle the entire brick work in order to make the necessary repairs. In addition to the cost involved, this method frequently requires the shutting down of the furnace for several days. This objectional feature has often resulted in a furnace being operated much longer than it otherwise would, the consequence being the complete destruction of the brick lining.

To minimize these disadvantages and at the same time effect a saving in the cost of maintenance, several designs of furnace blocks have been constructed by C. W. Gates, Ltd., of Montreal, which have given excellent results. The most recent departure in this respect is the new type of arch block adapted to stoker arches, Dutch oven type of boiler setting, or H. R. T. boiler back arches, and large fire door arches, reverbatory and smelting furnaces. As illustrated in the sketch these arches are constructed on the unit principle, where any single block can be replaced without disturbing the rest of the brickwork. This is made possible by means of the self-supporting and suspended feature of interlocking and keying the various blocks composing the arch. The blocks are so designed that any one in the set can be removed and a new one inserted without destroying or dismantling the adjoining blocks.

In addition to the arch being self-supporting, an increased factor of safety—but one that is not absolutely essential except when repairs are being carried out—is the suspension framework provided. These are fabricated pieces of bar iron and built in truss form to insure lightness with strength, and yet permit of ample expansion and contraction without destroying the dovetail supports in the upper surface of the bricks. These truss cross bars are provided in numbers to suit the length of the arch, with longitudinal bars running at right angles to carry the bolts that support the arch blocks. The interlocking feature of the block has the added advantage of preventing the leakage of the gases through the intervening space. This particular type of arch can be applied separately or in conjunction with the side furnace blocks, also manufactured by this company.



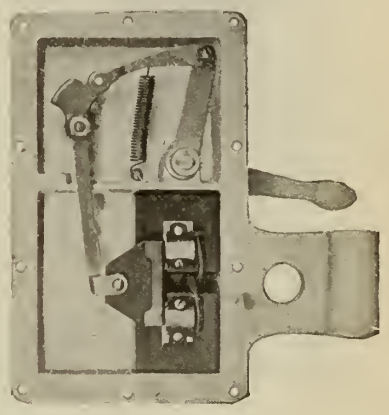
SUSPENDED ARCH FOR BOILER FURNACES.

ENCLOSED TANK SWITCH

THIS enclosed tank switch is of the single-pole double-break type, is instantaneous in action and suitable for use in tanks, etc., where regulation of liquid level between high and low limits is required. The construction avoids opening of the switch before the proper time and is free from the sticking and burning of blades that make trouble with a knife switch. No part of the casing or mechanism can become charged.

The regulation is obtained by a float operating the switch, which in turn actuates a solenoid controlling mechanical or other electrical devices.

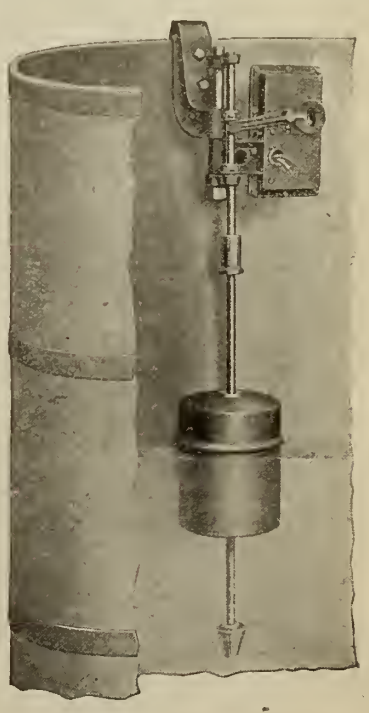
The case consists of a cast iron body and cover with corresponding flanged edges that permit the use of a gasket for damp proofing. The gasket makes it as nearly waterproof as any switch for



INTERIOR VIEW OF SWITCH.

its purpose can be. A substantial lug at one side of the back provides a means for standing to a supporting post.

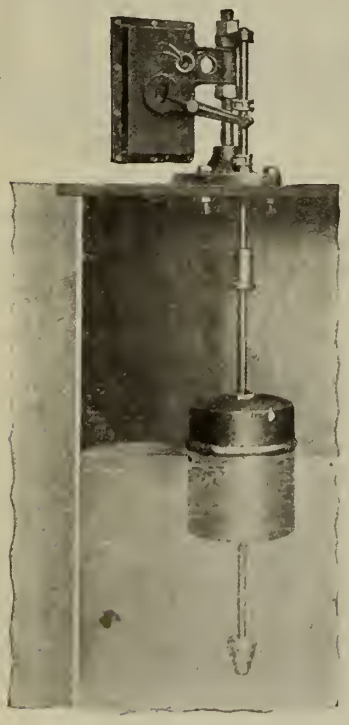
The internal electrical and mechanical parts are separated by an inside dividing partition which forms two separate compartments. A block of transite ebony asbestos bolted into the electrical compartment of the case supports the fixed contracts and also acts as an



INSTALLATION IN TANK.

insulating bushing for the incoming wires, which are brought through a boss in the back of the case. This boss is threaded to receive a ¾ in. conduit.

The fixed contacts are short cylinders of carbon held by set screws in ma-



chined brass terminals bolted to and insulated by the transite block.

The bolts which hold terminals and transite block together are countersunk and sealed at the back, and the wires are held by flanged binding screws on the sides of the terminal blocks.

The moving contact is a folded copper strip bolted to a piece of transite, which is loosely pivoted in the forked end of the cam lever. A flat spring within this fork keeps the contact piece always in correct position.

A float riding up and down on a guide rod hits a limiting stop on the rod. As it does so, the rod is carried up or down, and through collars upon its upper end imparts a corresponding movement to the switch lever. The length of travel of this lever is limited by a stop acting in a slot on the opposite side of the lever.

Movement of the lever oscillates a shaft and "grasshopper" lever, which in turn move a roller across a cam on the end of the electrical contact lever. The roller is held closely to the cam by a coil spring fastened to the dividing partition in the case. The tension of this spring throws the contact lever with a quick positive motion the instant the roller passes over the centre of the cam.

All internal levers are made of cast brass and are of substantial size and strength.

This device is manufactured by the Blackburn Smith Corporation, 105 W. 40th St., New York.

IMPROVED INSTRUMENT PANEL FOR THOMAS GAS METER

In order to place the total and graphic records of the gas flow furnished by the Thomas Meter in the superintendent's office or near the attendant interested in them, the Cutler-Hammer Mfg. Co., of Milwaukee, has recently developed a new design of instrument panel which requires but very little floor space. The earlier panels carried both the recording and regulating apparatus, but in the new arrangement the instruments are mounted on a separate small panel and the regulator may be located in some other part of the plant convenient for inspection by maintenance men. The meter housing is, of course, located at a point in the pipe line where a measure of the gas flow is desirable. In accordance with the modern trend of safety first ideas, further refinements have also been made in the design of the instrument panel to make it practically fool proof and shock proof. The new design follows the dead front principle of switchboard construction, as the accompanying illustration shows. The top section contains the galvanometer, which differs from the usual form of laboratory instrument in that the number of sensitive parts has been reduced to a minimum, and those sensitive parts that are neces-

sary are made easily replaceable, while all other parts are made very strong and durable. The mechanism and connections are placed in an aluminum case and are arranged so that the sensitive parts are well protected, but accessible. It is constructed jointly by the Leeds & Northrup Co., and the Cutler-Hammer Company. Most forms of galvanometers are placed in wooden cases and are so constructed that they do not give good service when used by unskilled mechanics.

The middle section contains the Easterline graphic watt meter, which records in standard units the flow of gas through the meter housing. Below the Easterline instrument is a Westinghouse single-phase watt meter, with scale calibrated for thousands of cubic feet of gas, which shows the total gas flow Mounted on the back of the centre section is a square D quick knife switch, operated by a lever on the front of the section, which serves as a main line switch for the heater circuit and all control circuits. At the left of this switch is mounted a push button control switch, which operates a C-H single pole remote control switch. This switch is magnetically opened and closed and mechanically locked and is used to open the heater circuit in the meter housing to permit the operator to balance the meter. The instrument panel also contains a current transformer, for all except the small sizes of meters, and fuses for the recording circuits and test connections for electrically testing the two watt meters. These watt meters are standard 5 ampere, 110 or 320 volt instruments, hence they may be tested for accuracy in the same manner as any other standard indicating or integrating electrical instrument, that is, by connecting them in series with similar meters of known accuracy. Test constants are stamped on each meter and it is not necessary to shut off the gas or interrupt the gas measurement to test the recording and integrating instruments. All live parts are enclosed in the enclosing case upon which the sections of the panel are mounted and the complete panel is furnished with a cast iron sub-base necessitating no other work in installation than the mere lagging of the base to the floor.

BAFFLE PLATES

In most forms of water-tube boilers, baffle plates are placed among the tubes at different points, to regulate the flow of the furnace gases and direct them so as to secure the greatest possible amount of heat absorption. These baffle plates undoubtedly add to the efficiency of the boiler when they are correctly placed, and it is therefore important, each time the boiler is cooled down sufficiently for a man to examine them, to see that they have not become displaced. Some of the tiles of which they consist may have fallen out or become broken, or the baffles may become otherwise displaced, as a whole or in part. In any case of displacement a passageway is likely to be opened for the flue gases, which will be shorter and easier than the one they are supposed to follow, so that a considerable fraction of the gases from the furnace will pass to the chimney or stack by a short cut, and without giving up as much of their heat as they are supposed to yield when the baffling is in good order; and of course this means a loss of efficiency.

The Operators' Point of View

The Power Plant is a Good Field for Ingenuity

Makeshift Gaskets and Packings Can Often be Extemporized From Most Unpromising Material—Ingenuity Helps, Even in the Washing of Hands

By J. E. NOBLE

A GREAT many power plants are located in small towns and villages, a large percentage of these plants keeping little or no supply of manhole gaskets, etc., on hand for emergencies. The engineer should persist in bringing such a condition to the attention of the owner or manager, putting such a notice in writing at least once, keeping a duplicate of the notice in his own possession in case of trouble along this line.

In most cases there is no store in such villages and towns handling power supplies, and it becomes necessary to send to the nearest city for the goods required. Altogether likely the telegraph will be used, with the possible result that the wrong goods will be sent on account of insufficient data, which means a further delay. In such a case, where a manhole gasket gives out, a substitute of some kind will be used; this may take the shape in a piece of hose, a red leaded gasket of twisted hemp, or some other makeshift. If it is possible to secure a piece of composition lead pipe, such as is used in gas work, a good substitute gasket can be had by drawing a piece of asbestos rope, or a piece of oil-soaked cotton rope, through the pipe to act as an equalizing cushion.

Sometimes you run across pointers in the small plants which the big fellows never hear about. One such came under my notice some time ago. Very often, even in big plants, hand cleaning soap is not supplied by the owners, and unless the engineer buys the soap himself he is apt to use the strong lye soap and caustic soda supplied by the owners for rough scrubbing and cleaning, with the consequent result of chapped hands for the engineer in cold weather. If the engineer will buy a bar of ordinary castile soap (25 cents) and get a box of fine sand, he will be fixed up for about six weeks. First soap the hands, then take a little of the sand, and a few rubs will take off every bit of dirt with absolutely no harm to the hands. This works better even than using coal oil and soap.

We often see it printed in the technical journals that it is a mistake to use paint, red lead, or pipe joint compound inside pipe fittings, that these things should be placed on the pipe thread only, thus doing away with the danger of getting some of the "dope" under valve seats in steam traps, etc. Under certain conditions I am against this advice; personally I believe that all new work should receive a good coating of lubricant, which is the principal use for any mixture used, much more so than as a filler) both inside the fitting and on the pipe thread, in this case the threads have every chance of screwing up into a tight position with the minimum amount of twisting strain. Under these conditions one thing must be done, whatever the pipes are to be used for they must be properly blown out before the main or finishing connection is made. Not for a minute or two but for a few hours. I remember reading an article once by the manager of a large concern who installed power plants. His advice was to blow steam through all new work for 48 hours to remove every particle of dirt, grease, red lead, white lead, iron filings scale, turnings and dirt generally. His statement concluded by the following: "Of course this wastes a lot of steam, but it is paid for a hundred times over in the avoidance of subsequent trouble."

INTERNAL COMBUSTION

By R. M. Murray

I often wonder why it is that woman is nearly always the medium chosen by the poet for his romance while empire-building romances are left unsung.

But perhaps the word poet is only a name that should in reality be applied to many other types of people.

The engineer, for example, is a mighty dreamer, but unlike the poet, he dreams about the force of machinery instead of the force of love.

Let us take as a comparative picture the Eastern dream of the magic carpet and I think you will agree that the result in practice is a wonderful achievement.

The dream in effect you will remember was that an individual might travel long distances easily and faster than the most speedy horse of Arabian legend. Stevenson's engine was an attempt to achieve this wish for speed, but it has developed into too heavy a vehicle to hold a true place in romance. Too many people are required for the management of a railroad train.

The internal combustion engine, however, as used on a motor car, motor cycle, or aeroplane is a vastly different proposition. It can be maintained by a single person, and it realizes the Eastern dream by enabling one to travel vast distances at great speed.

Consider also the simplicity of the engineer's dream in this particular instance. The engine in question is just a metal cylinder into which gas is drawn from a carburettor and ignited by electricity produced by the magneto. The downward stroke of the piston draws in the gas. The upward stroke compresses it, and the electricity fires the charge, producing what is called the working or driving stroke, after which the return stroke of the piston forces the exhaust gases out of the cylinder.

This cycle of operations is continually repeated, which fact gives the engine its name—the four-stroke internal combustion engine.

The four stroke internal combustion engine—it is indeed a true king in the world of romance. It has opened up for the future the possibility of learning the secrets of the unknown spaces. In the years to come everyone will have the opportunity of becoming a knight of the air.

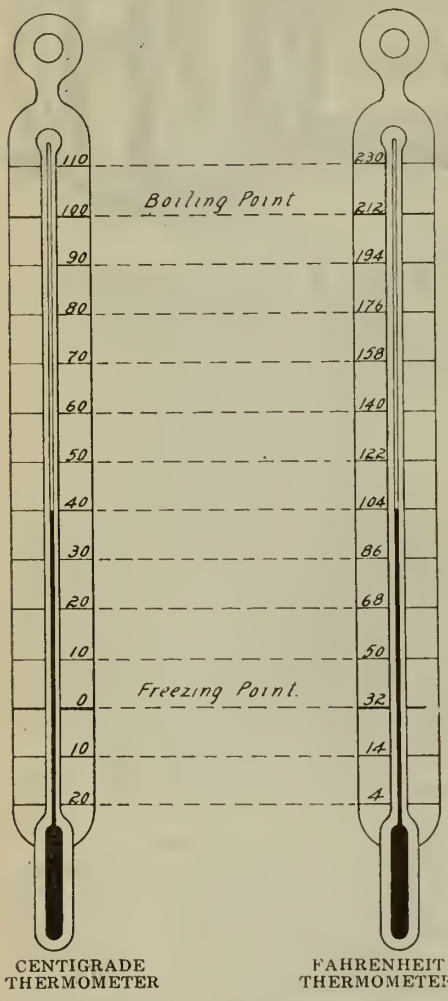
Think it over and judge for yourself whether the poet and engineer are not equally great dreamers and whether engineering is not truly one of the world's romances.

THERMOMETER SCALES

By T. L. Smith

When the term 40 degrees C. is used how does this correspond to the heat in Fahr.? The diagram shown in Fig. 1

answers this question graphically. To the right are shown the Fahr. temperatures, and to the left the corresponding



C. temperatures. From this picture it is evident that a temperature of 40 deg. C. corresponds to a temperature of 104 deg. Fahr.

ROPE AND TACKLE

Ropes are so frequently used that everyone should be thoroughly acquainted with their proper selection, care and employment. In using a single and double block or two double blocks taking a ¾ inch rope, the rope should be of good length, especially if the blocks are double and triple. Such a tackle may be used to lift timber to place or in putting up timber frames and trusses and in hauling up rafters. In hauling a heavy object on the ground the tackle should be so fitted up that the rope which is pulled runs from the object to be moved and not towards it. Ropes which have a woolly appearance, or where the ends of the fibre protrude, should not be used for important work. All ropes should be protected from dampness. Ropes are frequently allowed to unravel at the ends and thus become shorter. If a piece of twine is wrapped round it this might easily be avoided. When a rope runs over a pulley it is constantly bending and straightening, causing the fibres to chafe at the centres. The smaller the pulleys the worse it is. A pulley should not be less than eight times as large in diameter as the rope, and a larger one would be better. Ropes used in tackles or pulleys will give more service if they are reversed occasionally. For such important work as hoisting tackles it is better to use a four-strand woven around a cord. This costs more than the three-strand, but is worth more.

Knots weaken a rope; the more bends there are, and the shorter they are, the worse.

One principle of a knot is that no two parts that would move in the same direction if the ropes were to slip should lie alongside each other. Another is that a knot must be so devised that the tight part of the rope will bear on the free end in such a manner as to pinch and hold it.

To untie a hard knot in a rope or strap, hammer it on all sides with a piece of wood, then dip it in boiling water for a moment or two. A little soap will help. With a sharp-pointed instrument the knot may then be picked loose.

To remove a snarl in a rope, draw out one end as far as possible, then open the centre of the snarl so it can form a hole round this free end, and seize the entire bundle, forcing it through this hole, putting the outside first; this will add to the free ropes, and if continued will unravel any tangle.

PROPER HEATING OF BUILDINGS PROMOTES HEALTH

By J. E. McCormick

I HAVE just received from a nerve specialist in New York a booklet entitled "The Prevention of Colds, Influenza, Grippe, Pneumonia, and Tuberculosis." Incidentally, the author thereof passes a few remarks on the subject of "Heating" and of "Humidity." I have been wondering whether or not some of his remarks might not be of sufficient economic importance to be worthy of consideration by engineers in charge of heating plants. I have never given much attention to the heating and ventilation of buildings. My chief concern along such lines has been to prevent long lines of pipe from bursting during temporary shutdowns in cold weather, therefore I am not competent to judge of the above matter, neither am I at present in a position to give it a proper try-out. I shall quote from the booklet chiefly such parts as might concern engineers in heating plants. In some instances the booklet contains several paragraphs between the parts I have selected. I quote:—

"(a) When a fluid or moisture evaporates, a chill is produced. As an example: Moisten your finger and blow against it, you will observe that the side you blow against will feel cold."

"(b) The degree of chill produced through evaporation depends directly upon the rapidity of evaporation. The more rapid the evaporation, the greater the chill."

"(c) The rapidity of evaporation depends mainly upon the degree of dryness of the air coming in contact with the fluid or moisture. Free air always contains a varying amount of moisture. The less moisture it contains the more readily it will absorb moisture, and vice versa."

"From the foregoing it should not be deduced that moist air always feels warmer to the body than dry air. This applies only when the temperature is above 60 degrees or thereabouts. At lower temperatures the reverse is the case, that is, cold moist air feels colder than cold dry air, for the same reason that cold water feels colder to the skin than air at the same temperature."

"Perhaps the most common cause of colds is the disregard for the degree of humidity in heating and ventilating our living rooms."

"As an example of the influence of low humidity, I shall cite a condition that existed at the U. S. capitol at Washington, D.C., during the winter of 1913-1914. In the hall of the House of Representatives there was a mysterious "chill." Frequent complaints were made and many illnesses resulted. The engineers forced the temperature up to 77 degrees, but still the chill remained. In the Senate hall, on the other side of the building, there was perfect comfort with a temperature of 68 degrees. Finally, after a thorough investigation, it was found that the chill in the House chamber had been due to low humidity. Tests showed that the humidity at times dropped to 20 per cent. In the Senate chamber it was nearly 40 per cent."

"Not one room in a thousand is properly humidified. It is only in our large public buildings that the state of humidity is given any attention."

"The question arises: 'What is the proper humidity for a living room?' It is agreed that from 50 per cent. to 60 per cent. is not too high. High humidity combined with high temperature is extremely depressing, but if the temperature is kept below 70 degrees, the humidity may be 70 per cent. or even 80 per cent. without causing discomfort."

"For the bodily comfort, therefore, it is necessary that our rooms be kept reasonably moist. Since we feel far more comfortable in a room heated to 65 degrees and with a humidity of 50 per cent., than in a room heated to 75 degrees and with low humidity, we could save at least 33 1-3 per cent. in heating expenses by keeping the air in our homes and buildings moist."

"To humidify a room of average size it requires that about a quart of water be evaporated daily. This produces a humidity of about 50 to 60 per cent."

"Health lies in the mean, and not in

the extreme. This applies especially to heat, cold and humidity. It should be our aim to keep the body comfortably warm, cool, moist and dry, which means a humidity of about 50 per cent. and a temperature of about 64 degrees. Of course, it is impossible to meet these conditions at all times, but we can at least endeavor to do so."

The "saving in heating expenses" paragraph took my eye. It must be remembered, however, that the maintaining of a few extra degrees of heat throughout a building in New York City means a greater proportional expense than would the same few degrees in a similar building located in our colder Canadian climate. Nevertheless, if any such saving can be made in that place an appreciable saving might perhaps be obtained in Canada by the same means.

The author of the booklet mentions methods of humidifying air. Among other things he says: "There is sold in most house furnishing stores a special tank, which may be suspended from the back of the radiator. The heat from the radiator evaporates the water in the tank and thus moistens the air." The question in my mind is: "If thermo hydroscopes, or else hygroscopes, were installed in addition to thermometers and means were provided whereby the engineer could control both the humidity and the temperature, would this result in an appreciable lowering of the heating expense and at the same time provide a more healthy atmosphere for the residents to live in? Will someone who has studied heating and ventilation and has been in charge of house heating plants, please give us his experiences on this subject?

ASHES AND ASH-PITS

The ash-pits should be kept as clean as practicable, because if ashes are allowed to accumulate there, they not only interfere with the combustion by checking the draft, but also lessen the downward radiation of heat from the grate bars, which are then likely to become overheated, warped, and burned.

In plants of considerable size, in which large quantities of coal are burned, it is usually profitable to handle the ashes by a mechanical conveyor of some kind Convevors are most commonly employed for this purpose when the coal is handled in like manner, and the boilers are fired by mechanical means.

The ash-pit openings in boiler fronts are often left unprovided with doors. We strongly advise that doors be fitted to them in all cases, because the additional control over the draft that these doors afford is often of extreme value and importance. Under ordinary running conditions, however, the ash-pit doors should be left open and the draft should be controlled by the damper, because this procedure tends to keep the ash-pits cooler, and to prolong the life of the grate bars.

Do You Know That

At the end of 1917 there were about 140 electric furnaces installed in Great Britain, and the number has been considerably increased since then.

* * *

That a leading British trade journal contemplates the sending of its overseas circulation to the British Dominions and Colonies and the great trade centres of the world by air as soon as it is possible.

* * *

The extremely minute globules of oil, which are often present in feed water from condensers, are only about 1-1000 millimeter in diameter, and pass through the finest filtering medium. Their removal has been accomplished by means of the action of electric current, which causes these globules to coalesce and to combine into larger droplets, which can be successfully filtered out. The same inventor has also devised an apparatus for removing dissolved air.

* * *

The oxy-acetylene process has been successfully applied to the burning of holes in the mass of solidified iron called a salamander, which accumulates in the bottom of a blast furnace. Instead of drilling holes for dynamite, with the aid of a diamond bit, the hole is sunk by means of oxy-acetylene. As the cutting action of the gases continues, the pressure blows the molten material from the hole. It is found that one tank of oxygen is sufficient to sink a hole four feet deep.

* * *

Germany, during the war, made transmission belting out of steel and paper. Steel belts have been in more or less common use for a number of years, but the use of paper for transmitting power is at first sight somewhat of a startling innovation. The belts are made by several different processes. Some are made of plaited or knitted paper yarn, and thus have no transverse threads, making the edges very strong and eliminating fraying. Other belts are woven or knitted in tube form, and afterwards flattened out and stitched together.

* * *

In a hand-fired furnace about one-half the combustion takes place in the fuel bed, and one-half in the combustion space. The fuel bed acts as a gas producer and a gas retort; in it the solid fuel is gasified by the combustion of the fixed carbon and the distillation of the volatile matter. The gases rising from the fuel bed contain, at times, as much as 32 per cent. combustible, and no free oxygen to burn it. Hence, to burn these gases, air must be admitted over the fuel bed and mixed with the combustible gases, and the mixture burned in the combustion space. The oxygen flowing through the grate is all used up as it passes through the first three or four inches of the fuel bed.

Coal low in volatile matter is the best for hand-fired power plants in the prevention of smoke.

* * *

Although the form of the U. S. standard thread on paper looks very much unlike the Whitworth form in practice there is very little difference. The square top and bottom of the U. S. Standard are hardly ever found in ordinary commercial screws made by taps and dies or rolled. The crests of the threads in a tap or in a cutting or rolling die soon become rounded by the corners overheating and wearing away—and thus a radius is arrived at which closely approaches that of the Whitworth thread.

* * *

Helium, only slightly heavier than hydrogen, has been successfully used for filling arships and balloons. Its scarcity formerly kept the price up to $1,700 per cu. ft., and its only known source was from radium bearing ores. Since the war started however it was found that helium was present in large amounts in the natural gas of Texas and by liquefying this gas it could be recovered in a very pure state. Its main advantage over hydrogen was in its non-inflammability and it thus removed the greatest objection to the airship.

* * *

While the onion is the last thing one would imagine to have a practical use in the machine shop, it has been successfully used as a tempering medium replacing oil. The smell, as may well be imagined, is rather pronounced, but the results secured are very good. The method employed is to place the article to be tempered in a metal basin filled with chopped onions until it is quite cold. The onions can be used repeatedly. Small articles may be inserted in onions large enough to hold them. Garlic might do in a pinch, eh? The Germans are responsible for this latest atrocity.

* * *

Since the outbreak of war many new uses have been found for the metal magnesium. In combination with aluminium and other metals, it produces an alloy with a specific gravity about half that of aluminium, which is largely used for aeroplane work. On the other hand, if the weight has only to approach that of aluminium, a considerable admixture of heavy metals is possible; an alloy containing only 10.30 per cent. of magnesium is stated to have great strength. The formulae of some compositions containing magnesium and aluminium recommended for use in automobile and aeroplane construction, are given in Metallurgical and Chemical Engineering. Reference is made to a recent patent claiming that 92 per cent. of magnesium and 8 per cent. of aluminium gives an alloy of specific gravity 1.75, with a strength equal to that of gunmetal.

Take Agency.—The Yeates Machinery and Supply Co. have taken over the Canadian agency for the McCrosky Reamer Co., of Meadville, Pa.

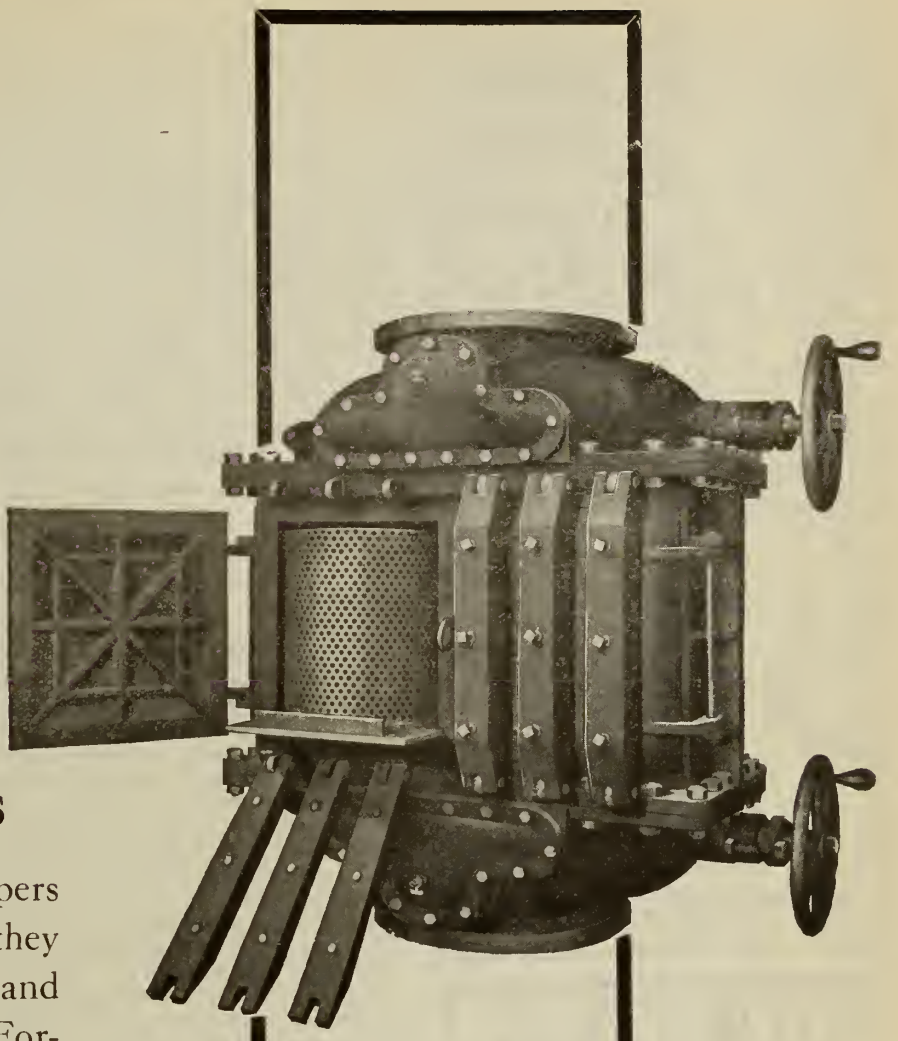
A True Fish Story

Yes sir, it's true that thousands of fish were caught in a few days time out of the water supply to a certain well known city by



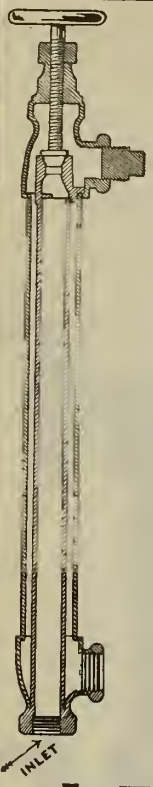
Twin Strainers

"Screens" is what the newspapers called them and in few days they trapped several large perch and several thousand minnows. Formerly these fishes went through the pump and were ground up into the domestic water supply. Ugh! It makes us quail—but it was true.

Minnows are fine for bait but poor as a component part of water used for drinking or steaming purposes. Twin Strainers kept them out and Twin Strainers will keep all of your water clean for they work *continuously*—two baskets, when one fills up you turn a valve and throw the other in without letting any water slip by unstrained.

Twin Strainers will handle water, oil or any other liquid. Everything about them is clearly explained in our complete Bulletin A. Glad to send you a complimentary copy if you'll send your name and address.

ELLIOTT COMPANY
443 Diamond Street, Pittsburg, Pa.



The LONG Patent Steam Trap

Automatically drains jacket kettles, separators and steam mains. Nine hundred to 1,500 feet of one-inch pipe isn't beyond its ability. Also used with splendid success in drying room systems.

Only One Movable Part

Works against 1 and 200 pounds of pressure—no possibility of freezing. Has two outlets so it can be installed in any position.

Circular gives full particulars.

Write to-day.

ENGINEERING

London.—The formation here of one of the greatest electrical combines in the world, to be known as the English Electric Company, with a capital of $25,000,000, and employing 25,000 persons, is viewed as a British effort to obtain ascendency in a market in which the Germans, as well as the Americans, have hitherto offered the most serious competition. One of the largest manufacturing concerns in this country, which has been one of the greatest producers of war materials, contemplates the manufacture of typewriters on a scale sufficient to be a serious competitor in the world market, where American manufacturers have had the monopoly.

Ottawa.—The annual general meeting of the Engineering Institute of Canada opened at Ottawa on February 10th, attended by engineers from all parts of the Dominion. The professional meeting followed the general, at which a number of engineering and national topics were discussed. A number of the leading engineering bodies of the United States were represented, and addresses were delivered by these representatives: Comfort A. Adams, president of the American Institute of Electrical Engineers; A. D. Flynn, secretary of the United Engineering Council of New York; and Doctor Ira Hollis, past president of the American Society of Mechanical Engineers.

HISTORICAL REVIEW OF STEAM TURBINE PROGRESS

The Westinghouse Electric and Manufacturing Company have just issued their Circular 1591, subjected, "An Historical Review of Steam Progress." This publication was written by Mr. Francis Hodgkinson, whose commercial and engineering knowledge of the steam turbine is perhaps as broad as that of any man in America. The circular is a reprint of an article which appeared serially and is now gathered together in one publication with the intention of becoming a handbook on steam turbine progress. The early history of steam turbine engineering is gone into and the earlier machines installed in America are illustrated. From 1899 until 1917 each year's development is probably recorded as it occurred and the improvements noted. The booklet is profusely illustrated with views of all the different types of impulse and reaction turbines and the construction of blading, valve chamber, governor, throttle valve, coupling, and oil cooler are shown in detail. This publication should be a valuable addition to designing and consulting engineers and is being used extensively in the Government training classes for junior engineers on steam engineering work.

BOOK REVIEWS

Graphical and Mechanical Computation. by Joseph Lipka, Ph.D., John Wiley and Sons, Inc., New York; the Renouf Publishing Co., Montreal. Price $4.00. A book written as an aid in the solution of a large number of problems which the engineer, as well as the student of engineering, meets in his work. In the opening chapter the construction of scales is developed and leads to a discussion of the principles upon which the construction of various slide rules is based. The second chapter develops the principles of a network of scales, showing their application to the use of various kinds of co-ordinate paper and to the charting of equations in three variables. Engineers have recognized for a long time the value of graphical charts in the lessening of the labor of computation. Among the charts devised none are so rapidly constructed, nor so easily read as the charts of the alignment type. Chapters III, IV and V give a systematic development of the construction of alignment charts; the methods are illustrated by charts for a large number of formulae. It is the writer's hope, as expressed in his preface, which we quote, that the simple mathematical treatment employed in these chapters will serve to make the engineering profession more widely acquainted with this time and labor saving device. Many formulae in the engineering sciences are emperical, and the value of many investigations is enhanced by the discovery of laws connecting the results. Chapter VI is concerned with the fitting of equations to emperical data. Chapter VII considers the case where the data are periodic, as in alternating currents, sound waves, etc. Where emperical formulae cannot be fitted to experimental data, further computation can be made by interpolation differentiation, and integration by the methods developed in the last two chapters. Numerous illustrative examples are worked throughout the text and exercises are given at the end of each chapter. While a preliminary knowledge of mathematics is essential to the complete understanding of the subject matter of this book, it places in the hands of the designing engineer a powerful means of simplifying the calculation of problems arising every day in structural, hydraulic, power plant, mechanical and electrical engineering. The treatment adopted throughout is concise and well arranged.

BOOK REVIEW

"Mechanical Drawing," by Ervin Kenison and Edward D. Waite, the American Technical Society, Chicago

The work of the accomplished engineer or designing draftsman is something which demands broad acquaintance with engineering and necessitates considerable ability and inventive skill. The same men who show such skill have had to acquire it through careful and painstaking study and practice of the rudiments of mechanical drawing. They had first to lay their foundation for the more advanced work along this line of equipment necessary for drawing of various kinds and how to use it. All of these important features are carefully treated of in this work. The studies are illustrated by diagrams and plates, and describe for students the simplest drawing problems to those which in difficulty approach more on the architectural and engineering fields. A portion of the book is given over to the description of necessary tools and their proper use. The method of the actual making of mechanical drawings is taken up in detail. In this part of the book much attention is given to geometrical definitions and constructions, as it is recognized that they are the foundation for much engineering work which finds its way to the drafting board. Altogether this book should prove to be a welcome aid to those who are beginning the study of engineering or architectural drafting.

CATALOGUES

The Howard Iron Works, Buffalo, N.Y., has issued a catalogue on their Howard expansion joint. The catalogue is descriptive of the various types of expansion joints made by this firm, and illustrations show the features of each type.

The H. Mueller Mfg. Co., Sarnia, Ont., have in the course of preparation a 300-page catalogue on water, gas and steam brass plumbing goods. This catalogue is at present in the printer's hands and will be ready for distribution within a few weeks.

The Ohio Blower Co., Cleveland, Ohio, have issued a small pamphlet on their Swartwout vacuum traps, which gives considerable detail regarding the operation of its mechanism. The trap is described and the method by which a number of loose parts are eliminated is shown very clearly by means of a cross section. The principle on which the trap works is also very clearly explained.

The Tallman Brass and Metal Company, Limited, Hamilton, Ontario, have issued their new stock list, dated February 1st, of brass and copper rod, tobin bronze rod, phosphor bronze rod, bass and copper sheet, tubing, etc. This stock-list is unusually complete and lists a great variety of sizes in the articles mentioned above and a number of other products of the Tallman Brass and Metal Company such as sheet copper, finished brass goods, automobile trunks, and electric fixtures.

The Goldie & McCulloch Co., Galt, Ont., have recently issued a catalogue on rotary jet condensers and vacuum pumps. This firm have obtained the rights to the Rees-Roturbo pumps and condensing equipment and this catalogue deals with the various types of condensing equipment which they are prepared to supply. Condensers in general are treated of. Condenser plant economies and the economy of high vacuum are shown. The Rees-Roturbo jet condenser is treated of in detail, its design being gone into thoroughly, and features of installation being dealt with in very thorough manner.

The Goldie and McCulloch Co., Galt, Ontario, have issued a very attractive catalogue on the Rees Roturbo pump, for which they have secured the manufacturing rights for Canada. The Rees-Roturbo pump has proven highly efficient and is widely used in Great Britain, Canada, and the United States. the high efficiency and self-regulating features proving particularly attractive. The literature, which has recently been published by the above mentioned firm, goes into the design of this pump very fully, and makes very interesting reading, the fundamental principle of the pump itself is very clearly explained and the manner in which the problems connected with variation of head in either the suction or delivery are dealt with is clearly shown. The various types of single and multi-stage pumps are featured and dimensions and other information given concerning their design.

The Harvey Hubbell Co., Toronto, have issued a new catalogue on their electrical specialties. This catalogue features the many electrical specialties manufactured by the firm, and the many possible combinations of interchangeable sockets, pull switches, attachment plugs and plug receptacles are illustrated in chart form, and in such a manner that it is an easy matter to make up any particular combination which might be desired.

Across the top of the chart pages appear illustrations of various socket caps, wall and ceiling bases, and down the first column on the first page of each set is a series of socket and pull switch bodies. The rest of the page bears complete views of numerous combinations made up of these interchangeable parts. In addition to the above, the catalogue illustrates the other specialties manufactured by the firm, such as special sockets, both brass and porcelain, and particularly Hubbell reflectors for industrial illumination. These reflectors are shown in such a manner that it is a very simple manner to pick out the proper reflector for any particular work.

NON-CORROSIVE
CYLINDER OIL
MANUFACTURED ONLY BY
E. H. KELLOGG & CO.
NOS. 242 & 244 SOUTH ST. NEW YORK, U.S.A.
FRICTION LOSS

An overload is often a necessity. But it is hard on an engine. To successfully carry an overload so that there will be no after effects on the engine a very careful selection of your oil should be made. An oil that is not free from impurities will cause a greater wearing on the bearings, a great friction loss will occur. You will need to fire the boiler more often because the engine will be harder to run. In this manner you lose out. You work harder, have larger operating costs, and less power all because of your oil. Do as a great many Canadian engineers have done — give Kellogg's "Non-Corrosive Cylinder Oil" a trial. Absolutely pure. Write us regarding it.

STEAM TRAP

WHY WASTE STEAM?

Wasting steam wastes coal, labor and money; inadequate, complicated, inefficient steam traps waste steam and labor.

Steam Trap SARCO is so simple, so efficient, so inexpensive that it saves money investment when it is purchased, saves labor and money on installing, then keeps right on saving steam for years and years.

Steam Trap SARCO is the cheapest trap sold; also the most compact, lasting and efficient. Adequate to any service from 0 to 200 lbs.; can't freeze or get out of order because steam closes it and condensate opens it; drains itself when steam is off, closes automatically when steam comes on.

Don't hesitate, don't even stop to investigate—simply send for one on 30 days' free trial—the trap will convince you. Write TO-DAY for Bulletin J-6.

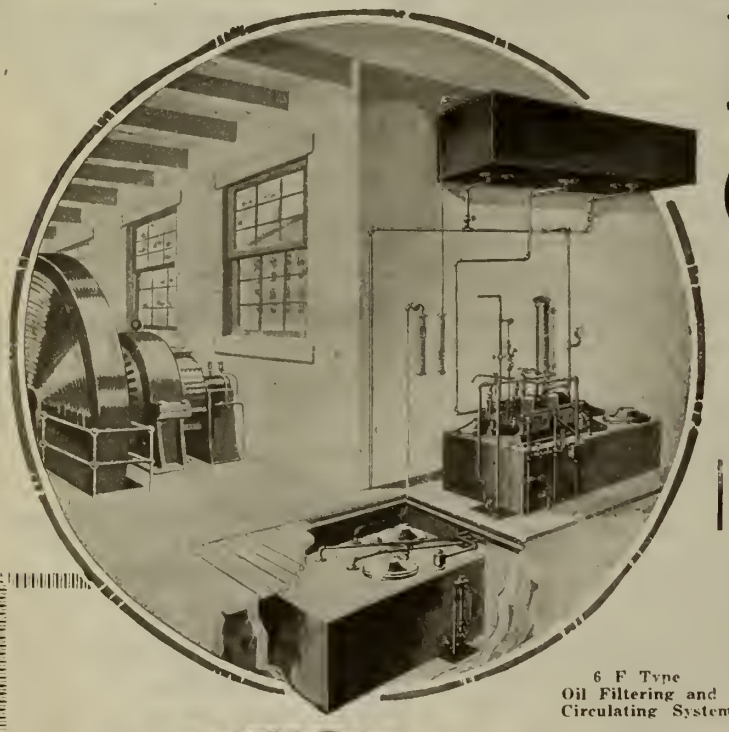
BOILER LOGIC

The Heine Safety Boiler Co., St. Louis, Mo., have just completed the printing of the latest edition of their "Boiler Logic," an 86-page treatise on steam boilers.

This treatise covers the following topics:—

1. Some fundamental considerations of boiler design.
   - (a) Furnace design requirements: mixing, time, temperature.
   - (b) Heat transmission from fire by radiation.
   - (c) Heat transmission by convection.
   - (d) Heat transmission through tubes and to water.
2. Practical baffling of water tube boilers.
   - (a) Flexibility of design.
   - (b) Leakage and cost of repairs and renewals.
   - (c) Active and inactive surface.
   - (d) Ease of cleaning soot and ash deposits.
3. Heine boilers for different fuels.
   Hand firing with Bituminous coal
   Hand firing with Anthracite coal.
   Chain grate stokers.
   Underfeed stokers.
   Oil fired.
   Firing and services.
   Shavings and refuse.
   Bagasse.
   Gas fired.
   Waste heat boilers.
   Dredge boat boilers.



6 F Type Oil Filtering and Circulating System

Results that Count

Wherever it is installed there is more uniform lubrication of machines, without loss of oil; less depreciation of equipment; fewer repair bills; a better spirit among employees, and—increased profits, all of which are good, strong reasons why the Bowser should be in your plant.

The Bowser stores and supplies new oil—collects dirty oil — purifies it, makes it good as new—returns the proper supply to points of use wherever located. Its simplicity, durability, and ease of operation are reasons for its popularity in all well regulated plants.

"Results that Count" always follow its use —we'll be glad to tell you more about it if you drop us a line.

BOWSER SERVICE

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive all offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

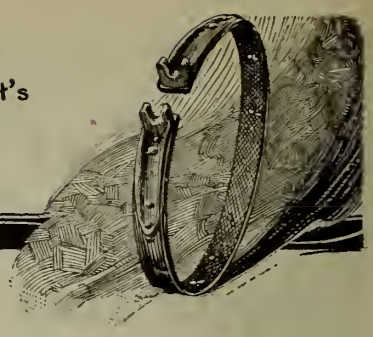
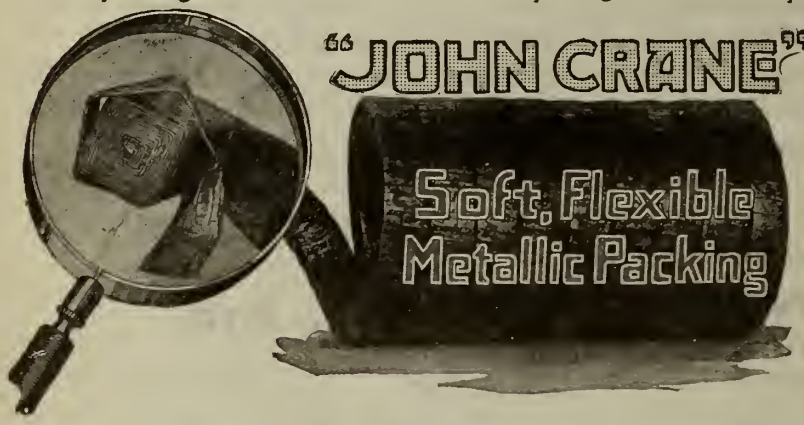
What is used for break lining?
Fabric (Asbestos) etc. Why? Because it grips!
Do you want packing to grip your rods and plungers? Of course not. That's what scores them, necessitating costly machining and replacements.
Then why, by all that's logical, do you use Fabric Packing? Think it over—



Here's An All Metallic Packing— Soft, Flexible and Compressible

"JOHN CRANE" is made of babbitt and therefore is as frictionless as your babbitted bearings. But by a patented process it is made flexible; compressible and so soft you can cut it from a coil with a knife. Thin babbitt foil, wound layer upon layer, with lubricant in between, that's the secret. With "John Crane" in your stuffing boxes and a small stock of "John Crane" in your stock room, your packing troubles are over.

This packing never hardens. Instead of pulling it out and replacing it, you simply add a ring when needed. You run no risks of shutdowns due to packing "blowouts" for no ordinary pressure can penetrate the multiple layers of babbitt foil.



Engineers who know "John Crane" use it for all services. It serves equally well on water, steam, or air, ammonia, oils, or even sulphuric acid. It will pay you to get acquainted with "John Crane" right now.

Order a few coils TODAY.

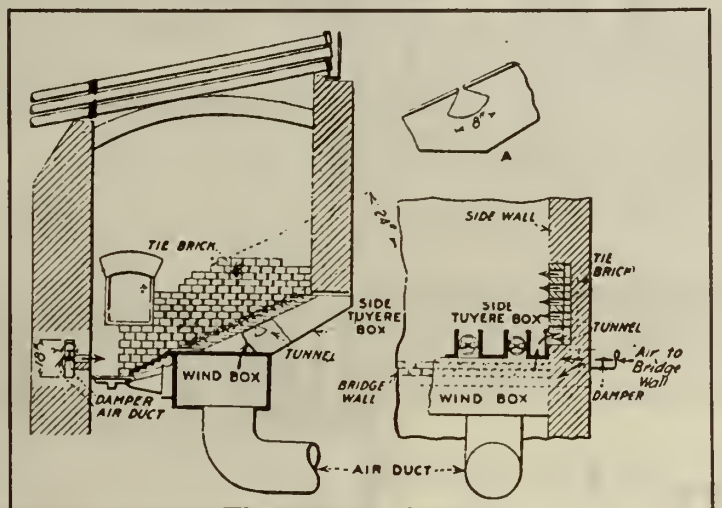
ADVERTISING to be successful does not necessarily have to produce a basketful of inquiries every day.

The best advertising is the kind that leaves an indelible, ineffaceable impression of the goods advertised on the minds of the greatest possible number of probable buyers, present and future.

Add Power To Your Furnace

by eliminating the fuel-waste resulting from the "freezing" of clinkers to the side walls. The Bernitz Method of constructing side walls with interior air passages through which cooling air currents are passed to keep the bricks below the fusing point will

Positively Prevent the Accumulation of Clinker Mass



The Bernitz System as applied in a Taylor Stoker Installation

The Bernitz Method

1. Saves coal by insuring more perfect combustion of the fuel used.
2. Increases boiler efficiency by shortening time spent in cleaning walls.
3. Increases efficiency by burning coal which formerly clinkered.
4. By shortening time spent in cleaning walls reduces influx of air through doors.
5. Saves B.t.u.'s usually lost by radiation through side walls.
6. Permits increased forcing of fires by eliminating danger of clinker "freezing."
7. Makes it possible to remove such clinkers as are formed without dumping fire.
8. By reducing manual labor in boiler room keeps laborers more contented.
9. By keeping fires clean insures greater uniformity in heat applied.
10. Is equally applicable to old or new constructions.

The Bernitz Method is licensed, not sold. It has received full patent protection in Canada and the United States and in foreign countries, and licenses under these patents are being granted on the basis of the H.P. rating of the boilers under which the Method is to be installed.

Why !

OIL IS MORE ECONOMICAL

IMPERIAL FUEL OIL is absolutely uniform. Every pound or ton will give the same heating efficiency. It provides more stable and steadier sustained heat, which greatly increases the power-capacity of boilers under which it is used.

Imperial Fuel Oil is highly concentrated. It is easy to handle and saves 40% of storage space. Coal is bulky and is never uniform. In storage, coal deteriorates rapidly and sometimes develops spontaneous combustion.

Imperial Fuel Oil does not deteriorate no matter how long you store it. With Imperial Fuel Oil grates and grate implements are eliminated, and all up-keep expenses are reduced. Considered from a standpoint of efficiency, convenience or economy, Imperial Fuel Oil is not approached by any other type of fuel for use in generating steam.

The fact that Imperial Fuel Oil is so highly concentrated, and that it is absolutely uniform, makes it the ideal fuel for steamships. It makes a big reduction in the boiler-room force possible and will increase the steaming radius and the available cargo space. Then, too, it means cleaner decks and cleaner equipment—pleasanter as well as more profitable voyages for all concerned.

For the heating of hotels, public buildings, schools and churches, Imperial Fuel Oil also offers many advantages.

Consult with Imperial Fuel Engineers, free. Write or call at Room 704, Imperial Oil Building, 56 Church Street, Toronto, Ontario.

Becoming a Bigger Man

WHAT is the difference between some men you know and others known to you? Why are some men earning $3,000 a year and some $30,000? You can't put it down to heredity or better early opportunities, or even better education. What, then, is the explanation of the stagnation of some men and the elevation and progress of others?

We are reminded of a story. A railroad man, born in Canada, was revisiting his home town on the St. Lawrence River. He wandered up to a group of old-timers who sat in the sun basking in blissful idleness. "Charlie," said one of the old men, "they tell me you are getting $20,000 a year," "Something like that," said Charlie. "Well, all I've got to say, Charlie, is that you're not worth it."

A salary of $20,000 a year to these do-nothing men was incredible. Not one of the group had ever made as much as $2,000 a year, and each man in the company felt that he was a mighty good man.

Charlie had left the old home town when he was a lad. He had got into the mill of bigger things. He developed to be a good man, a better man, the best man for certain work. His specialized education, joined to his own energy and labor sent him up, up, up. To put it in another way: Charlie had always more to sell, and the world wanted his merchandise—brain, skill and ability. Having more to sell all the time, he got more pay all the time.

Charlie could have stayed in the old home town; could have stagnated like others; could have been content with common wages. In short, Charlie could have stayed with the common crowd at the foot of the ladder. But Charlie improved himself and pushed himself, and this type of man the Goddess of Fortune likes to take by the hand and lead onward and upward. Almost any man can climb higher if he really wants to try. None but himself will hold him back. As a matter of fact, the world applauds and helps those who try to climb the ladder that reaches towards the stars.

The bank manager in an obscure branch in a village can get out of that bank surely and swiftly, if he makes it clear to his superiors that he is ready for larger service and a larger sphere. The humble retailer can burst the walls of his small store, just as Timothy Eaton did, if he gets the right idea and follows it. It is not a matter of brain or education so much as of purpose joined to energy and labor. The salesman or manager or bookkeeper or secretary can lift himself to a higher plane of service and rewards if he prepares himself diligently for larger work and pay. The small manufacturer, the company director, the broker—all can become enlarged in the nature of their enterprise and in the amount of their income—by resolutely setting themselves about the task of growing to be bigger-minded men.

Specialized information is the great idea. This is what the world pays handsomely for. And to acquire specialized information is really a simple matter, calling for the purposeful and faithful use of time. This chiefly.

One does not have to stop his ordinary work, or go to a university, or to any school. One can acquire the specialized information in the margin of time which is his own—in the after-hours of business. Which means: If a man will read the right kind of books or publications, and make himself a serious student at home, in his hours—the evening hours or the early morning hours—he can climb to heights of position and pay that will dazzle the inert comrades of his youth or day's work

IF business—BUSINESS—is your chosen field of work, we counsel you to read each week THE FINANCIAL POST. It will stimulate you mentally. It will challenge you to further studious effort. It will give you glimpses into the world of endeavor occupied by the captains of industry and finance. With the guidance of the POST, and with its wealth of specialized information, you, a purposeful man, aiming to go higher in life and pay, will find yourself becoming enlarged in knowledge and ambition, and will be acquiring the bases and facts of knowledge which become the rungs of the ladder you climb by.

It is the first step which costs. But this cost is trivial—a single dollar. We offer you the POST for four months for a dollar. Surely it is worth a dollar to discover how right we are in our argument. If you have the will to go higher in position and pay, sign the coupon below.

750 H. P. Link-Belt Silent Chain Drive at mills of John and James Dobson, Inc., Philadelphia, Pa.

CHAIN the Load to the Prime Mover

GIVES you the most positive, most flexible, most direct application of power that is possible to secure.

LINK-BELT
SILENT CHAIN DRIVES

transmit 98.2% of the power to the driven machine. They eliminate belt slippage with its consequent loss of power and machine efficiency. They permit short center drives, thus saving floor space. They cushion the motor against sudden shock when heavy loads are applied and they protect and lengthen the life of the driven machine. They are "flexible as a belt, positive as a gear, more efficient than either."

Our 128 page Data Book No, 125 gives details on Link-Belt Silent Chain Drives up to more than 500 H. P. It also tells how to figure drives and prices. Send for a copy.

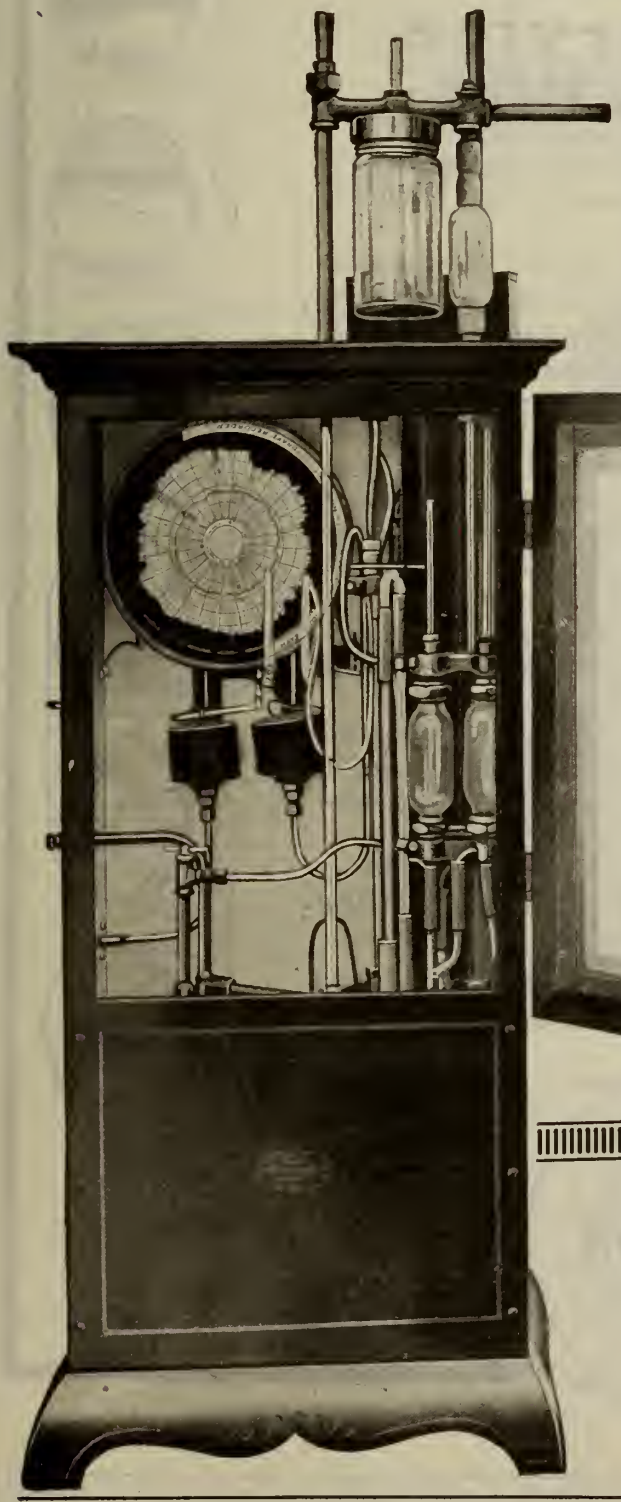
Hays CO_2 and Draft Recorder

Tell the Story of Boiler Efficiency

The exact reason why 30 to 50 per cent. more fuel is consumed in your plant than should be, is shown by the Hays CO_2 and Draft Recorder. With these appliances installed, your firemen can fire intelligently; they will work with accurate facts before them—instead of groping in the dark. For Hays CO_2 and Draft Recorder permanently record the story of efficient combustion



and Point Out Errors in *Firing, Draft, Boiler Settings, Etc.*

YOU

need this Hays CO_2 and Draft Recorder to fire your Boilers intelligently

Hundreds of plants are using these Hays Appliances and saving 30 to 50 per cent. of their fuel expense as a result.

The Hays Recorder is automatic, self-adjusting, infallible. It does not depend on hand adjustment and mechanical action for accurate operation. Indications are controlled by rising and falling columns of mercury, water and caustic potash.

We invite you to investigate, believing the facts will convince you that these Hays Appliances would quickly earn their cost in your plant.

Dominion Rubber System Belting Service is Dominion Wide

No matter what your business or where it is located, there is within telephone distance of your plant, a branch of the Dominion Rubber System and a belting expert.

These technical experts are not merely salesmen, ***they know belting*** and its requirements thoroughly and their services are at your command without charge, whether you are a customer or not.

The Dominion Rubber System's belting men have worked out successfully many seemingly impossible belting problems, and whether your difficulties are actually due to belting or some more remote cause they will help you to solve them.

Put your problems up to the Dominion Rubber System experts ***—place your belting equipment in their care—they will shoulder the responsibility*** for giving you efficient service in all your belting, no matter what it is used for.

They are able to "speed up" your production—reduce your manufacturing or belting costs or eliminate unnecessary delays and "shut downs."

The Dominion Rubber System is not only the largest but the oldest organization of its kind in Canada and has specialized in belting for more than fifty years—its entire facilities and Dominion Wide Service are at your command.

If you are in trouble or in doubt about a belt, 'phone, wire or write our nearest branch and ***let us prove our Belting Service means more than just selling belts.***

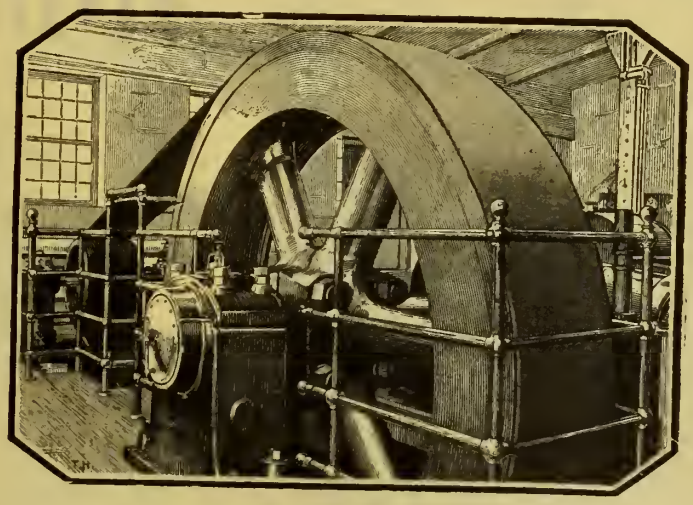
GRATON AND KNIGHT



GRATON AND KNIGHT

Doing the thing that "Couldn't Be Done"

This Graton & Knight Spartan 24-in. double belt was installed in July, 1912, on a generator drive in the plant of the Bosch Magneto Co., Springfield, Mass. The extremely short pulley centres caused some belting men to throw up their hands and say, "It can't be done." But this Spartan Belt has been doing it successfully for more than six years. Now, note its low cost. At the purchase price per foot, the bill figures ninety-six cents per week or .004½ per delivered horsepower per week.

The above result, at so low a cost, is due to the Graton & Knight standardization—using the right belt for the work to be done, at a price that it ought to cost—no more and no less. Economy in belting means the longest and best service possible under given conditions. We make all kinds of leather belting for all uses—large or small.

The nature of the drive always governs the wear of any belt. Two belts of exactly the same quality on two different drives will make showings varying greatly in length of service. Using Graton & Knight Standardized Series Leather Belts means full delivery of power for every dollar invested.

The G. & K. idea is economy through standardization. It means the right belt in the right place.

For example, Spartan—the belt illustrated—is especially adapted for hard drives, high speed, intermittent loads and where belts are subjected to the action of steam, oil, water and other agencies destructive to ordinary belting. It may be that you are using too good a belt for some purposes and belts not good enough for another. Cost Equalization will spell Economy for you in capital letters.

One factor in the solution of *your* belting problems is the use of belting made from properly tanned leather. The hide of a steer is Nature's tough, elastic, resilient protection during years of activity. G. & K. tanning *preserves* all of those qualities. Nothing can really take the place of the matted *fibre* of leather which locks and unlocks in response to the demands of expansion and contraction, to the very end of its life.

It will save you money to let us recommend belts for every drive in your plant. Then, in buying, call for "Graton & Knight—Brand or equal." This does not commit you buying our belts. It does put your buying on the one economical basis—that of the work to be done.

Voorhees Rub-Steel Valves
The Valve with a Backbone

The BEST for Boiler Feed Pumps

A perfect and permanent adhesion of rubber and steel. Gives **lasting support** against conditions that discredit all-rubber types, make all-metal a source of continual annoyance and emphasize the complexity of other combinations.

The **simplest** valve to instal. No extra equipment involved in interchange with other valves.

No pumping heat too great for our "Superhot" Grade.

Ask for special booklet.

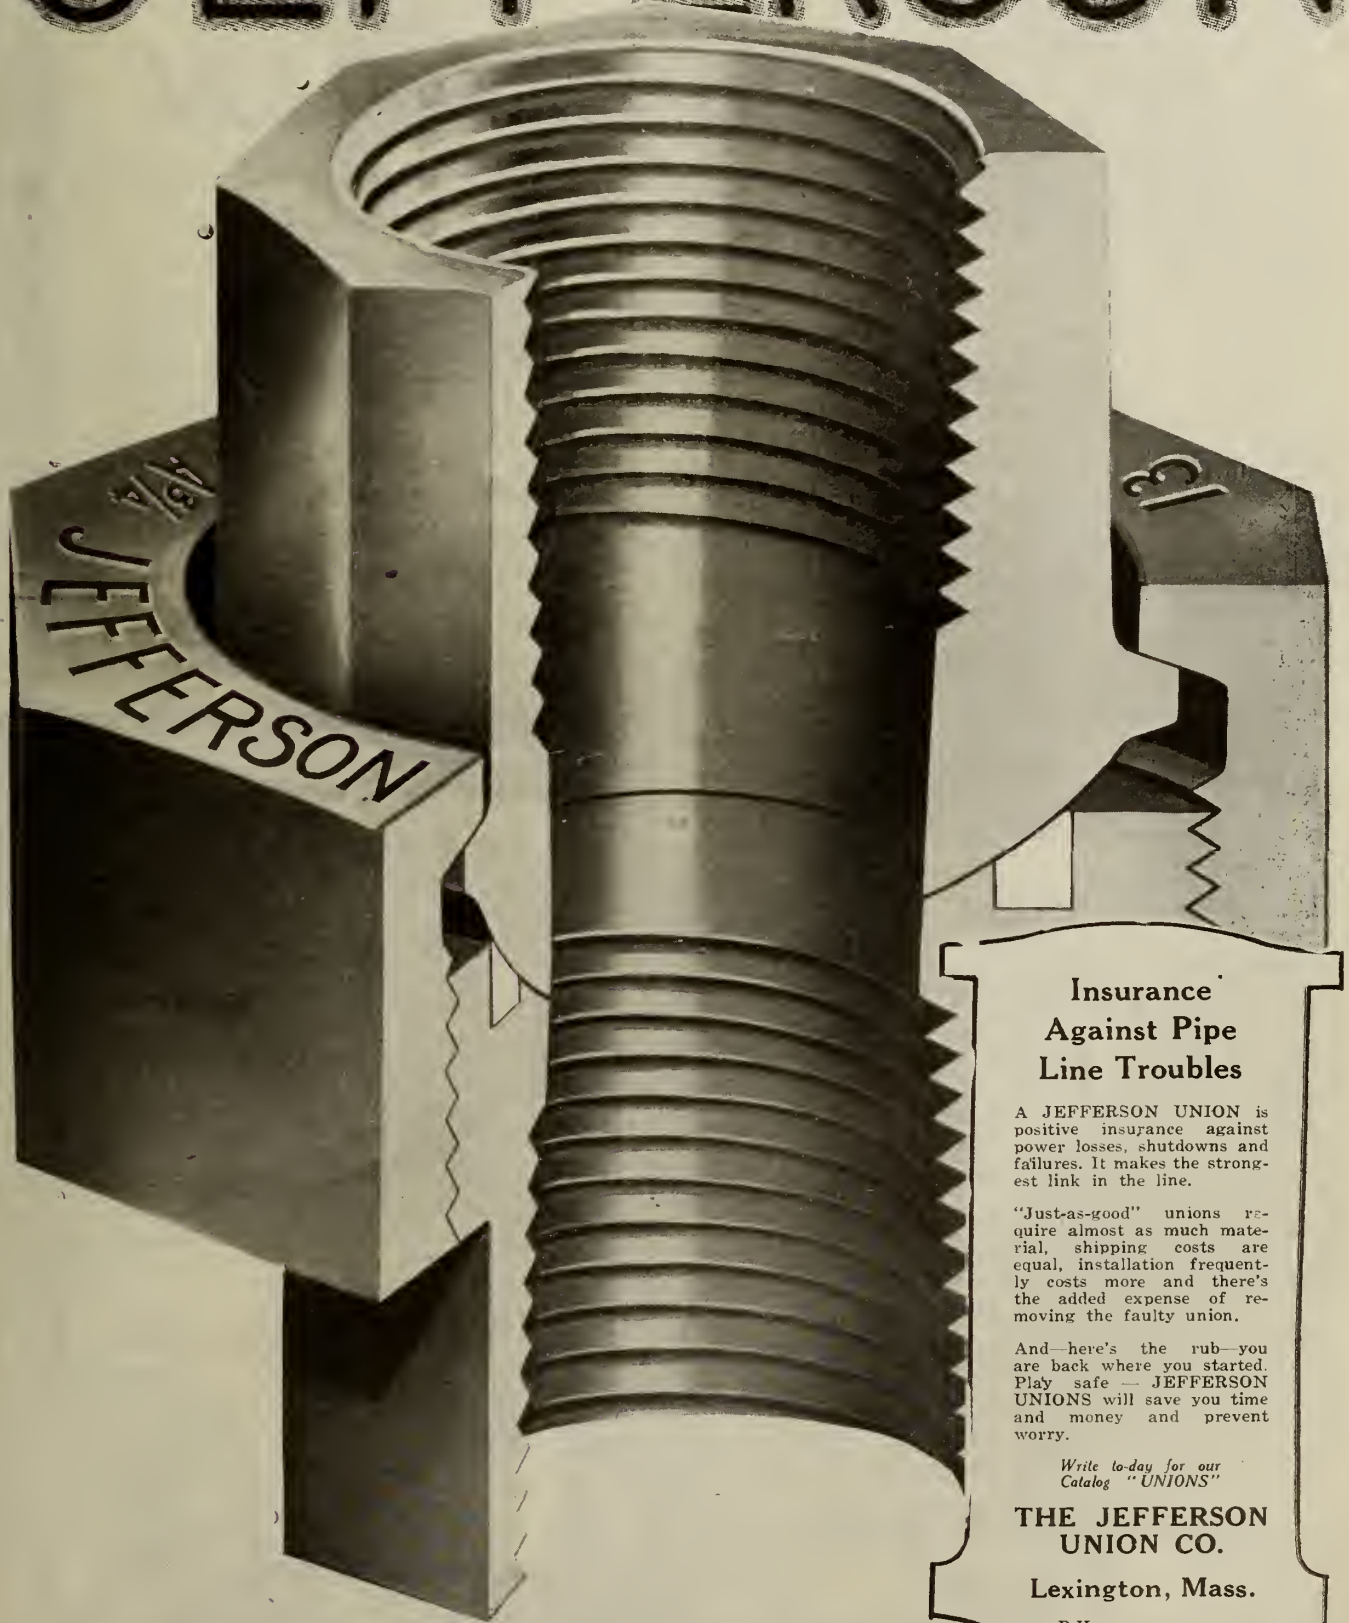
JEFFERSON



Insurance Against Pipe Line Troubles

A JEFFERSON UNION is positive insurance against power losses, shutdowns and failures. It makes the strongest link in the line.

"Just-as-good" unions require almost as much material, shipping costs are equal, installation frequently costs more and there's the added expense of removing the faulty union.

And—here's the rub—you are back where you started. Play safe — JEFFERSON UNIONS will save you time and money and prevent worry.

Write to-day for our Catalog "UNIONS"

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically ***eliminates expensive shut-downs***. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

Boiler Room Efficiency Instruments

NO MORE GUESSING IN YOUR BOILER ROOM
THE DEFENDER SYSTEM (READS)

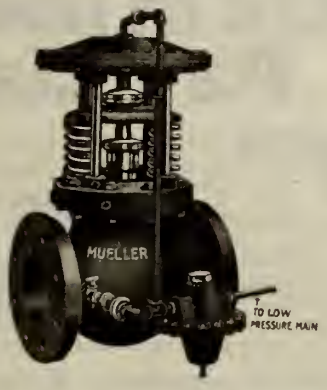
Draft, Temperature and CO_2 on each Boiler. Determine the Draft over the fire and at the last pass of the Boiler and the drop in Draft through the Boiler—that gives the highest percentage of CO_2 in the Flue Gas and the lowest Flue Gas Temperature.

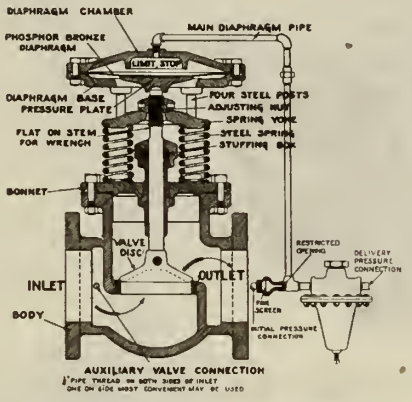
This gives the highest Boiler and Furnace Efficiency. The Defender Catalogue No. 10, which is just off the press, shows a very complete line and price list of Combustion Appliances and Damper Regulators for the Boiler Room.

The Defender Automatic Regulator Co., 709 Pine St., St. Louis, Mo., U.S.A.

MUELLER Reducing and Regulating Valve

SINGLE SEAT; AUXILIARY OPERATED





E5030 for Water, Gas and Air
E5130 for Steam
(Flanged or Screwed)

Very Popular with Shipbuilders

USES

This valve is for use on exacting installations. It will make any desired reduction and will maintain a constant delivery pressure regardless of fluctuations of the initial pressure.

CONSTRUCTION OF STOCK REGULATORS

All valves have iron bodies, bronze stem and stuffing box, phosphor bronze diaphragms, seats of composition suitable for the required service; iron diaphragm chamber and steel springs. The main valve is controlled entirely by the small auxiliary valve. This auxiliary valve closes and opens the main valve by admitting initial pressure to, and releasing it from, the diaphragm chamber of the main valve according to the demand of the delivery side. Regulators of this description are suited for pressures up to 150 pounds, and will be furnished at above prices. When regulators are required for pressures in excess of 150 pounds we will furnish suitable material. Prices upon application.

STRAINER

In all cases it is advisable to use a strainer to prevent obstruction from grit, scale, cuttings, etc. Blow out pipes thoroughly before installing valve.

INFORMATION IN ORDERING

In ordering give highest and lowest initial pressure and required low or delivery pressure, approximate quantity or volume to be used per minute, size of high pressure pipe and low pressure pipe.

In ordering flanged end valves give diameter of flanges and bolt circles and the number and size of bolts.

INSTALLATION

Note.—Any proper working regulator acts as a check valve. Where the building up of the pressure is to be avoided use our diaphragm operated relief valve E5060.

We will not be responsible for improper selection of valves.
Consult us regarding the best type for your service.

ENGINEERS Are in the Big Pay Class

You can get into the big pay class too and make the chief's salary your own if you will take advantage of this opportunity.

The Library of Steam Engineering—packed full of the very things an engineer must know—will fit you to pass the engineer's license examinations and help you to step up into the biggest kind of job, and it won't cost you a cent to use them for one whole week.

Engineers—Assistants—Firemen and Oilers all need these great books, written by the greatest authorities in the profession. They will bring you more usable information in your spare time than you can get in years of the old-time, learn-by-doing methods.

Don't Send Any Money You can have these books for 7 whole days without sending one penny. Just send us the coupon on the bottom of this page today. All 7 volumes will come to you at once, express collect, and you can have a whole week to examine them and use as if they were your own—give them every test you can think of and send them back if you want to. If you want to keep the books just send us $2.00. You can send the balance the same way —$2.00 each month until the special price of $21.80 is paid.

Part of What They Contain Construction and Types of Boilers—Boiler Accessories—Boiler Practice—Steam Engines—Indicators—Valve Gears—Locomotive Boilers and Engines—Air Brakes—Steam Turbines—Gas and Oil Engines—Gas Producers—Chemistry of Combustion—Heating and Ventilating—Elevators—Refrigeration—Compressed Air—Dynamo and Electric Machinery—Generators—Motors—Power Stations. 3300 pages and 2500 pictures and diagrams. Hundreds of tables and formulas.

Free Service With each set of these books a year's consulting membership in the American Technical Society goes free. The regular price is $12.00. You can send any of your problems to our experts and engineers, who will solve them free of anyc harge for one entire year.

Don't Delay Don't let another day pass before you take advantage of this offer. Sooner or later you will bump up against something where you will have to know what's what. Give yourself the best of it and don't take any chances. **SEND THE COUPON NOW.**

7 volumes, each 5½ x 8¾ inches; 3300 pages; 2500 illustrations; full page plates, diagrams, etc.; hundreds of tables and formulas. Flexibly bound in American Morocco and trimmed in gold.

There Is But One Plastic Fire Brick—

BETSON'S

REG. U.S. TRADE MARK PAT. OFF PLASTIC FIRE BRICK

We pioneered this field and overcame the difficulties. There is nothing mysterious about Betson's; it is merely an exceptionally high-grade compounding of the best fire clays, using the special mechanical preparation which we have found essential for making a satisfactory one-piece, formed-in-place furnace lining.

Betson's comes in bulk in barrels, in a plastic condition, ready for use, and can be placed by almost anyone. No need to wait for shipments of fire brick or special blocks, or for experts to lay them.

The largest industrial concerns, who run their boiler plants continuously are using Betson's. Durability and air-tightness are its great advantages, both due to the fact that there are no joints in Betson's, which forms a one-piece, monolithic lining for the whole boiler setting.

Try out a barrel or two in repairs to your present fire-brick linings, and when the time comes for relining you will replace with Betson's complete.

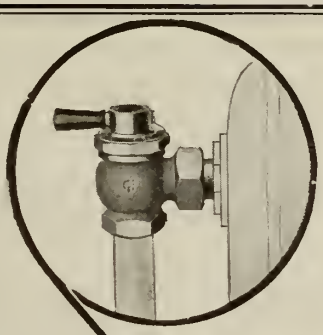
Heating Efficiency

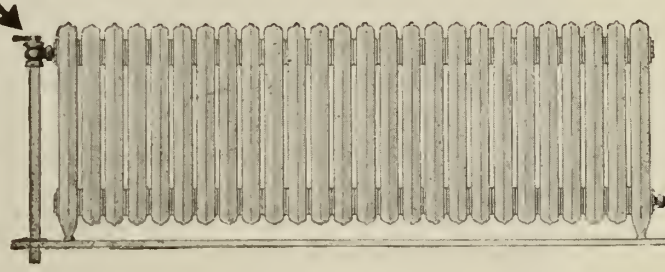
Two important elements of Dunham Heating Service are here pictured in their proper relation to the radiator.

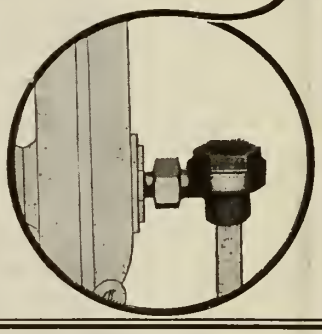
The valve is really packless. Seven-eighths of a turn fully opens or closes it.

The Trap is extremely simple: just three parts—a body, cover and a corrugated thermostatic disc secured in the cover. No loose parts, no sliding contacts, nothing to gum up, no guide or pin to obstruct the valve opening. It operates perfectly under conditions varying from 10 pounds' pressure to 15 inches of vacuum, without adjustments.



The DUNHAM HEATING SERVICE





Write for the interesting details of both the valve and trap.

Cutting the High Cost of Pneumatic Tool Hose

PNEUMATIC Tool Hose is an important item of expense in your business. Not so much in its actual cost as in the frequent need for renewal.

Ordinary Pneumatic Tool Hose is built with one idea only—to carry air pressure.

But the thing that wears out pneumatic tool hose is not the work it is designed for but the usage it receives.

So Goodyear has produced a new pneumatic tool hose—a hose that is protected against **wear.**

It is built with an outer cover of tough white rubber—of a grade that can be used for treads on automobile tires.

This cover will resist wear—the daily dragging over ship plates, steel girders, cinders—under any of the conditions to which pneumatic tool hose is submitted.

It will stand up also under unusual shocks and blows.

Thus Goodyear Pneumatic Tool Hose will yield longer service—service that means important economies.

A hose purchase may bob up in your place any day. Write or telephone the nearest Goodyear Branch. Ask to have a hose specialist call—with samples. No obligation—you need not be immediately in the market for hose. Tear out this ad. and file for easy reference.

Handle it Mechanically

If any advertisement interests you, tear it out now and place with letters to be answered.

"The Mysterious German Onions"

On nights when the German air raiders were out, they sent up strange, luminous balls behind their lines and anchored them above the clouds—globes of fire which could be seen for forty miles or more. What these "onions" were, or how they were kept in stationary position above the clouds, is still a profound mystery. The Allies never learned anything about them, but the Allied night bombing crews steered their course to the Rhineland by the luminous buoys thus provided.

What is known about the onions is told by Lieut. J. Vernon McKenzie in the course of an article, "Raiding the Rhineland," in MARCH MACLEAN'S. It is an intensely interesting article, telling all about the great reprisal campaign which implanted the fear of war in the German civilian heart.

"NO HOPE FOR THE WETS"

"Already the temperance forces are lined up to stop any possible break in the prohibition dam," writes J. K. Munro, in discussing what is going to happen at the coming session at Ottawa. He predicts that Union Government will hold together, but that the habit it has contracted of promising everything asked is going to make a lively session. He expects:

Dry legislation at the earliest possible moment.
The moral reform forces in control.
No change in the Divorce Law.
Tariff concessions made to the West.

The March number, in fact, is full of live, up-to-the-minute features.
The famous Canadian Ace, Lieut.-Colonel W. A. Bishop is on the cover.

Some of the outstanding articles and stories are:

The Transformation (a new serial)—By Frederic S. Isham.
A Canadian King-maker (the story of Lord Beaverbrook in Britain)—By Maurice Woods.
Fitting in the Returned Soldier—By George Pearson.
The Three Sapphires—By W. A. Fraser.
The Strange Adventure of the Nile Green Roadster—By Arthur Stringer.
Fakers—and Others—By E. Ward Smith.
Lend Me Your Title—By Onoto Watanna.
A Shady Deal—By Archie P. McKishnie.
The City of Lost Laughter—By Mary Josephine Benson.

"The Voice of Canada Interpreted"

A new department starts in this number given over to summarizing and presenting opinion in Canada on outstanding topics, as reflected in the press. In this issue the department is given over to a careful compilation of opinion on the problems of the returned soldier.

Events of the World in the Remaking

The Review of Reviews section of MACLEAN'S, which contains extracts from the best articles selected from all magazines the world over, includes in the March issue the following articles:

Diamond Soot Blowers at Plant of Buffalo General Electric Co.

These concerns find Diamond Soot Blowers a good paying investment because they effect the following economies:

1. Fuel; a saving of 4 to 8%.
2. Boiler efficiency; an increase of 4%.
3. Labor; a saving of many hours per day.
4. Longevity; an increase in the length of service of boiler tubes, through the prevention of corrosion.
5. Steam; a saving of 25 to 75% of steam used for cleaning.

If your boilers are not equipped with Diamond Soot Blowers—your friends are benefiting by lower costs of power than you enjoy.

For full information write for Bulletin 119.

922 POWER Vol. 48, No. 23

Coal Saving by the Scientific Control of Steam Boiler Plants*

By D. Brownlie

THE author has been associated for about ten years with the investigation on scientific lines of the working of every description of steam-boiler plant, and in the present article it is proposed to give the average figures for 250 typical steam boiler plants, with the object of supplying accurate data as to the tremendous national economy that can be effected by the adoption of scientific methods in the boiler-house.

In the burning of coal for the generation of steam, the loss because of lack of scientific methods is hardly realized and, apart from the national point of view, offers to the individual firm a means of most substantial economy in running expenses.

It is not possible to find out what is the exact amount of coal used for the production of steam for purposes other than power, there being, for example, no statistics available showing the number of steam boilers at work in Great Britain.

The author proposes therefore to assume, until further information can be obtained by a proper engineering census of the country, that the total amount of coal used for steam generation in the United Kingdom is between 75 and 100 million tons per annum, being 60 to 70 million tons for power production and 15 to 30 million tons for purposes other than power, corresponding to 40 per cent. to 53 per cent. of the total coal used, and is of the opinion that the 250 boilers to be dealt with in the present article are really representative of all the boiler plants of the country, and the results of such a very large number of exhaustive investigations carried on continuously during [illegible] as to judge with [illegible] rine" boiler, 2 "vertical" boilers, and 3 "patent" boilers difficult to classify. It would be most interesting to know the exact number of each type of steam boiler at work in the country, although there is no doubt that the chief type in use is the "Lancashire."

Amount of Fuel Used—The average shows 20.9 lb. of fuel burnt per square foot of grate area per hour, referring, of course, to the average amount burnt per hour per working day, and not to the amount for any particular hour. This figure is considerably below what is possible on a boiler plant run on modern lines, which would burn something like 25 lb. to 30 lb. per square foot grate area per hour with the average quality of fuel. The boiler plants of the country are working under very easy conditions in this respect, and much more fuel could be burnt per boiler. Figures for fuel consumption depend largely on the quality of the fuel. Thus a good quality washed coal of, say, 13,000 B.t.u. and 7 to 8 per cent. ash could easily be burned economically at the rate of 35 lb. per square foot per hour, whereas purely refuse coals would only give [illegible] Coke of good quality can be burnt [illegible] per square foot grate [illegible] 15 pounds.

[illegible] to the efficient [illegible] some other works.

Economizers—Out of the 250 plants, 155 were fitted with economizers, the other 95 plants having no means of utilizing the waste heat from the boiler flues.

Taking the 155 plants fitted with economizers, the average saving is 11.4 per cent. of the coal bill. The highest figure found was 19 per cent. on a cotton-mill plant. The ordinary figure obtained on a well-managed plant is 15 to 20 per cent. saving, depending on the conditions.

Estimation of CO_2—Out of the 250 plants, 225 [illegible] not [illegible] CO_2 recorded [illegible]

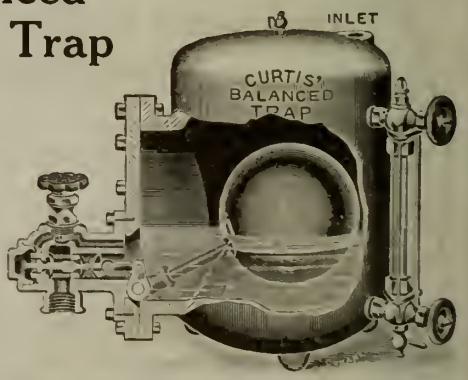
HOMESTEAD, PA.

CURTIS Engineering Specialties
Balanced Steam Trap



This trap is often used as a waterline trap on large plants where there is need to balance any particular circulation to prevent snapping and cracking in pipes and radiators.

This Trap Has These Points of Difference and Superiority

1. A perfectly balanced valve.
2. An absolutely frictionless valve.
3. The valve can be removed without breaking a joint, starting a gasket, or taking out a bolt.
4. The valve being frictionless and balanced, the whole power of the float is available for opening and closing the valve.
5. Each trap will operate perfectly on pressure varying from one to 250 lbs.

The great merit of this trap, its simplicity, its dependability and serviceability make it well worth being better acquainted with. Send for special printed matter describing it and giving prices. Address the Manufacturers.

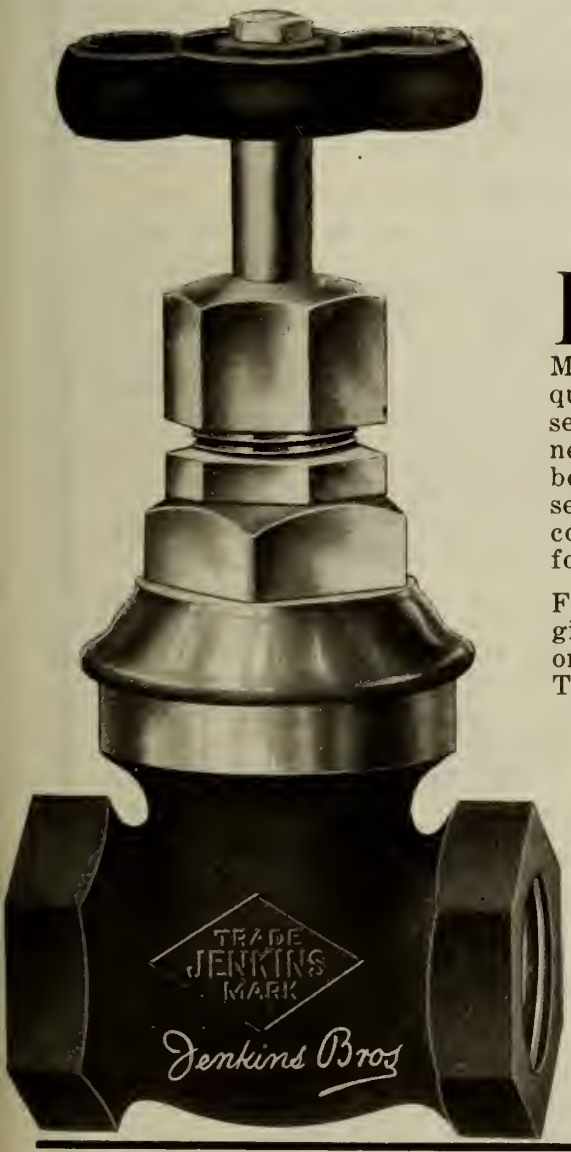
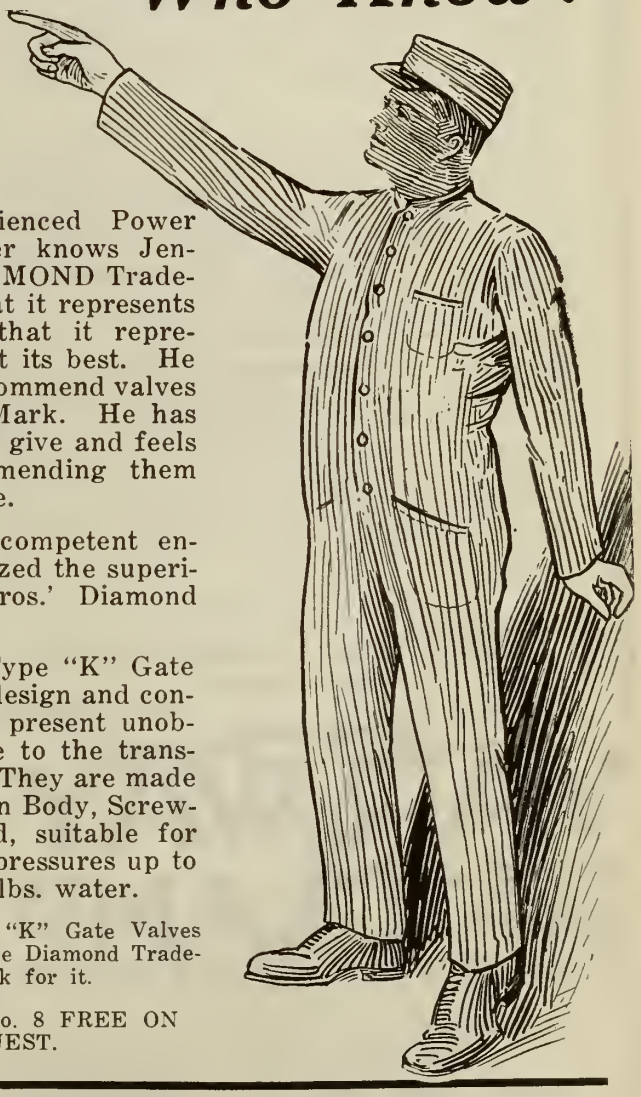
TRADE JENKINS MARK

Type "K" Brass and Iron Body Gate Valves

Appreciated by Men Who Know!





EVERY experienced Power House Engineer knows Jenkins Bros.' DIAMOND Trade-Mark—he knows that it represents quality—he knows that it represents valve service at its best. He never hesitates to recommend valves bearing this Trade-Mark. He has seen the service they give and feels confident of recommending them for any valve service.

For over 50 years competent engineers have recognized the superiority of Jenkins Bros.' Diamond Trade-Mark Valves.

Jenkins Bros.' Type "K" Gate Valves excel in design and construction. They present unobstructed passage to the transmitted medium. They are made in Brass and Iron Body, Screwed and Flanged, suitable for working steam pressures up to 125 lbs. or 175 lbs. water.

All Genuine Type "K" Gate Valves are identified by the Diamond Trade-Mark. Always look for it.

TRADE JENKINS MARK Jenkins Bros

There's a Big Waste in Little Leaks

Do you know that a one-tenth inch pipe-joint leak at 150 lbs. pressure will waste steam in a year at a cost to-day of approximately $825? Figure it out for yourself. Leak one-tenth inch; pressure 150 lbs.; 9 lb. steam per lb. coal; coal $5.50 ton; 10 hours per day; 300 days per year.

And it's such an unpatriotic waste in these days of coal conservation—such a needless and careless waste at any time—for the leak can be stopped in a few minutes' time with a YARWAY (formerly Simplex) PIPE JOINT CLAMP.

More than 13,000 leaks have been stopped since this effective clamp was first placed on the market. Millions of dollars have been saved. The saving in coal can only be guessed.

The Yarway (formerly Simplex) can be attached in a few minutes by any workman. The principle can be seen from the illustration shown here.

If there is a pipe-joint leak in any of your lines, tell us the size and we will send you a Yarway for 30 days' trial. Instead of returning it, you will probably be as enthusiastic over its success as the man who said of a Yarway Clamp, "It's worth its weight in gold."

Here Is a Good Formula

TO SAVE MONEY

$$C\left(0.98 - \frac{dn}{DN}\right) = \$ \text{ wasted per year}$$

Where—

C=cost of power per year for the given drive dollars;

d=diameter of driven pulley plus belt thickness, inches;

n=r.p.m. of driven pulley,

D=diameter of driving pulley plus belt thickness, inches;

N=r.p.m. of driving pulley.

If you don't like formulas, do it this way:

(1) Add diameter of driven pulley to belt thickness, inches, and multiply by r.p.m. of driven pulley.

(2) Add diameter of the driving pulley to belt thickness, inches, and multiply by r.p.m. of driving pulley.

(3) Divide (1) by (2)

(4) Subtract (3) from 0.98

(5) Multiply (4) by the cost in dollars per year of power for the drive.

The result is the dollars wasted per year because of unnecessary belt slip. These dollars can as well be saved by simply treating the belt with Cling-Surface.

Cling-Surface primarily stops slip. It also permits easy or slack running, thus permitting a belt to embrace the pulleys through maximum arcs. Hence Cling-Surface treated belts are doubly insured against slip.

Cling-Surface also makes the belt impervious to dampness and resistive to heat, cold, chemical fumes, etc. It reduces internal friction and adds greatly to belt life.

If you are at all interested in saving belt money you should take advantage of our trial offer. Order a 50-lb. can of Cling-Surface for a 30-day trial. Pay for it if you're satisfied. If unsatisfactory, the trial won't cost you a cent.

Sole manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

Stationary and Hoisting Engineers

Everyone operating a STATIONARY steam plant of 10 h.p. or over in the Province of Ontario must hold a Stationary Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Everyone operating a HOISTING steam plant working at a pressure of 20 pounds or over, irrespective of horse power, and used for hoisting in structural operations or excavating purposes, in the Province of Ontario, must hold a Hoisting Engineer's Certificate from the Board of Stationary and Hoisting Engineers. Anyone operating such a plant without a Certificate is liable to the penalties set forth in the Stationary and Hoisting Engineers' Act.

Application forms for obtaining STATIONARY or HOISTING Engineers' Certificates, may be had upon applying to the Chairman.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914 With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID,
Minister of Public Works and Highways

W. A. RIDDELL, M.A. Ph.D.,
Supt. Trades & Labour Branch

D. M. MEDCALF,
Chief Inspector of Steam Boilers.

W.D. ANDERSON'S Engineering EFFICIENCY SERVICE

Efficiency Methods installed in Industrial Plants by **PRACTICAL MEN** who thoroughly understand the subject.

GRAPHIC PRODUCTION CONTROL can be applied to any industry. It will completely revolutionize your **Production Problems.**

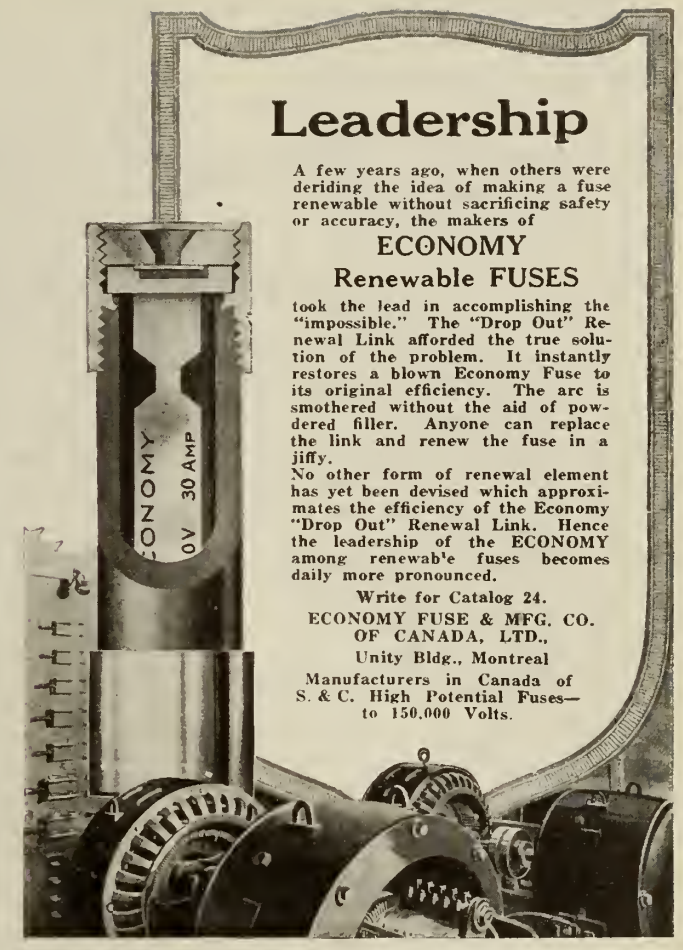
We will be glad to explain it to you, and point out the Economies to be effected by its introduction. It puts everybody on **Schedule. It stops Loafing on the Job.** It makes everybody a producer. It is working elsewhere and giving splendid results. Let us write you.

RING UP

Anderson's Efficiency Service

Phone: 221 Adelaide

380 Queen West, - Toronto, Canada



Leadership

A few years ago, when others were deriding the idea of making a fuse renewable without sacrificing safety or accuracy, the makers of

ECONOMY

Renewable FUSES

took the lead in accomplishing the "impossible." The "Drop Out" Renewal Link afforded the true solution of the problem. It instantly restores a blown Economy Fuse to its original efficiency. The arc is smothered without the aid of powdered filler. Anyone can replace the link and renew the fuse in a jiffy.

No other form of renewal element has yet been devised which approximates the efficiency of the Economy "Drop Out" Renewal Link. Hence the leadership of the ECONOMY among renewable fuses becomes daily more pronounced.

Write for Catalog 24.

ECONOMY FUSE & MFG. CO. OF CANADA, LTD.,

Unity Bldg., Montreal

Manufacturers in Canada of S. & C. High Potential Fuses—to 150,000 Volts.

The ANDERSON

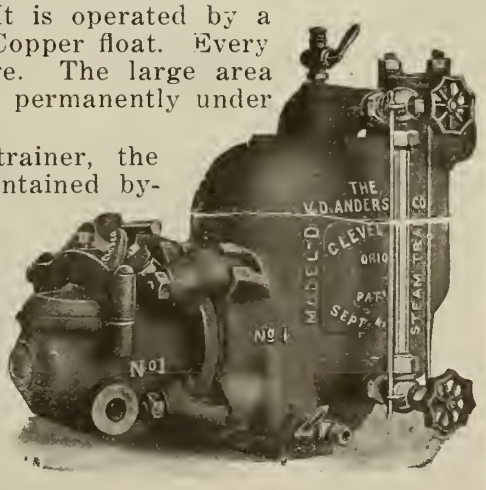
Model "D" Steam Trap

Stays Tight

Your condensation trouble may be an old standing problem that you have never been able to solve. Conditions in your plant may be unusual—extremely severe. Nevertheless, the Anderson Model "D" Steam Trap will stay tight from the day you put it in.

It will save you expense and trouble because it will work perfectly under high or low pressure. It is operated by a counterbalanced Lake Superior Copper float. Every part is machined to solid gauge. The large area valve will not wire draw and is permanently under deep water seal.

Moreover, the self-contained strainer, the outside gauge glass, the self-contained by-pass and complete accessibility to all parts are other Anderson features that make for high efficiency and low-cost service.



Write for Descriptive Booklet.

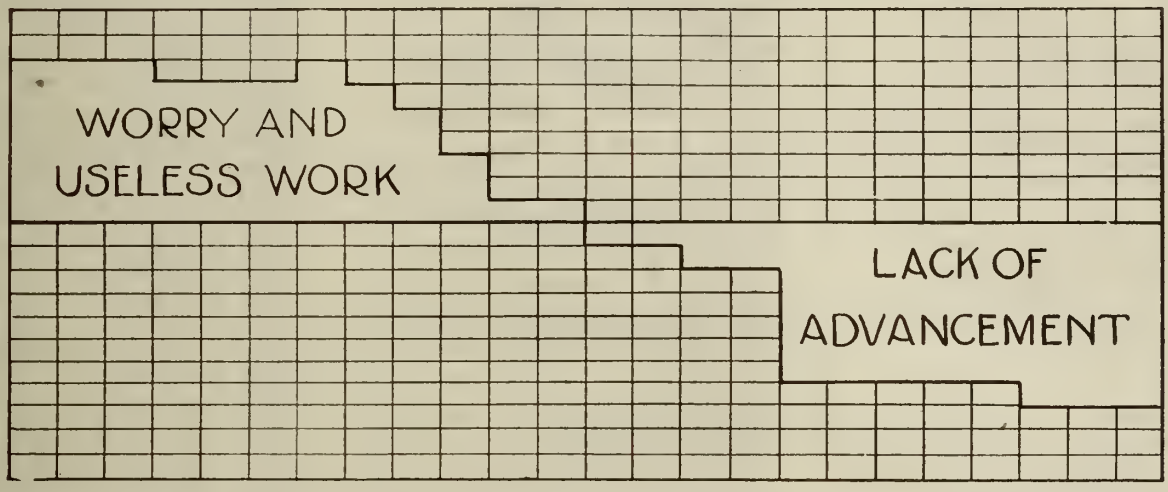
Let the C.A.S.E. Smooth Out Your Load Curve



Remove The Peaks of Worry And Unproductive Labor And Build Up The Valleys By Working For Your Advancement

A man who is thoroughly grounded in the practice of his profession, who is free from personal worry and trouble, overcomes the many difficulties besetting the path of the operating engineer with little labor and in a manner ensuring his advancement.

The successful man owes his success to a wise appreciation of the advantages and mutual help offered by association with those in the same field of endeavor. To join an association having for its objectives the welfare of the engineer in things mental and material, his advancement in knowledge and skill, his protection by provision for sickness and distress is to take advantage of an opportunity indispensable to all who hope to better themselves.

If you are interested in such an organization and live where less than fifteen engineers are located, send for a copy of our constitution and application blanks for admission to nearest branch lodge. If there are more than fifteen engineers in your community, get together and send for particulars regarding formation of a branch lodge.

J. H. HALE, General Secretary,

Canadian Association of Stationary Engineers

230 Caroline Street Hamilton, Ont.

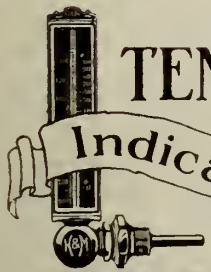
Tycos

TEMPERATURE INSTRUMENTS



Indicating Recording Controlling

Tycos Mercurial, Recording and Index Thermometers for all industrial and laboratory applications.
Electric Contact Thermometers.
Temperature, Pressure and Time Regulators.
Mercury Column Vacuum, Pressure and U Gauges.
Tycos Base Metal, Rare Metal and Radiation Pyrometers (Indicating and Recording)
Fery Radiation Pyrometers.
Hygrometers, Hydrometers.
Mineral Oil Testing Instruments.
Aneroid and Mercurial Barometers.
Recording Barometers.
Pocket Compasses.
Surveying Compasses, Rain Gauges.
Anemometers and Air Meters
Thermographs, Hand Levels.
Aviation Barometers and Inclinometers.
Tycos Sphygmomanometers.
Fever Thermometers and Urinary Glassware.
Thermometers of all kinds for home and general use.

Measuring up to high standard production implies an efficient indicating, recording and controlling of temperature changes. To meet the demand of efficient management in the details of power-house and factory, you are forced to have instruments in which you can place confidence.

Tycos fills the bill. *Tycos* Instruments are the product of over half a century of experience. They are exact to the **nth** degree—dependable, silent servants of efficiency.

Every line of service from the delicate fever thermometer for indicating temperatures of the body to the Fery Pyrometer, registering several thousand degrees, is represented in our plant. Unquestionably this wide range of experience is proof-positive of our dominance in this field. Write now for our interesting literature.

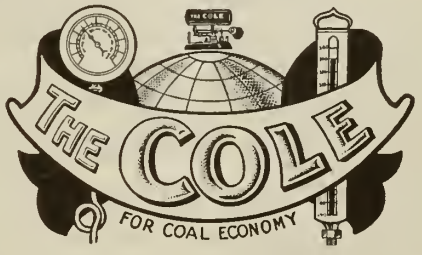
The Question Answered

See last month's Power House

Boiler Feeding Methods	Amount of fuel used lbs.	Saving of fuel over the amount required by pump feeding cold water
Direct acting pump feeding cold water.	100	0%
Injector feeding and warming the water average temp. (150 deg. F.)	98	2%
Injector feeding thru heater at average temp. 210 deg. F.).	93	7%
Direct acting feed pump feeding thru heater	88	12%
Power pump through heater	86	14%
		Over direct acting pump feeding with hot or cold water
Direct return boiler feed traps as before explained	14	86%



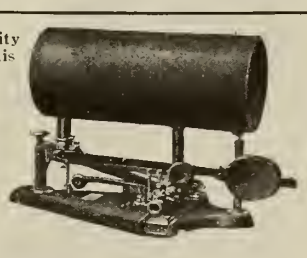
GEO. W. COLE, Limited, 2002 Dundas Street W., TORONTO
Also Mfrs. The "COLE" CHECK Valves

"Black Diamonds" are Precious

Save them

COAL is scarce. The supply is still limited. Scarcity means high prices. You should save every piece of this precious fuel as a measure of business economy.

Morehead Back-to-Boiler System
will Save 8 to 20% of Your Fuel.



It keeps condensation out of your steam lines by returning it to the boilers while it is HOT. In a year's time you save many tons of coal. The MOREHEAD SYSTEM gives freedom from steam troubles and maintains a uniform temperature throughout the plant. Requires practically no attention. Let us tell you more about the New Improved Morehead Trap.

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

INGLIS

BOILERS

Inglis Quality stands foremost. It has not been attained in a day or a month or a year or two. It represents the fruit of over half a century meeting the requirements of boiler users.

Inglis boilers are Canadian standard in materials, workmanship and efficiency. They ensure a lifetime service with a minimum of repairs.

We are also sole Canadian makers of Erie City Water Tube Boilers, Vertical and Horizontal.

Our representatives will be pleased to show installations of our different types of boilers to prospective customers.

Write for prices and specifications.

CORRECT LUBRICATION PAYS DIVIDENDS

YOUR power plant must be properly lubricated if it is to give you economical, efficient service. Correct lubrication pays dividends in the form of larger, steadier output and bigger profits. Maximum output is of vital importance in every industry. Correct lubrication is, therefore, a sound business necessity.

Every Imperial grade and brand is not only a high-grade lubricant, but each is carefully and accurately formulated for the exact purpose it is meant to serve. The proper use of Imperial lubricants insures a steady-running, efficient power-plant with every lubrication trouble eliminated.

Boilers

Waterous Return Tubular Boilers installed the Waterous way will give you the full steam value from the fuel you use.

Combined with the advantages possessed in general by this type of boiler—economy in fuel consumption, large steaming capacity, ability to use hard and dirty water, and comparatively low cost—we can furnish you with a boiler setting that is designed and dimensioned to best handle the fuel you use.

We build H.R.T., Locomotive, Vertical and heavy Marine Boilers all sizes.

Let us quote.

HOYT METALS

Don't use ordinary babbitts. The initial cost may be less than in using **quality** babbitts, but **quality** babbitts give longer and better service and are decidedly cheaper in the long run. Here is a babbitt of **quality**—the famous

FROST KING

There's no better babbitt metal made anywhere than "Frost King." It is an all round babbitt. Over 40 years of successful metal mixing are represented in production. It is the babbitt you should use for high speed and heavy duty.

NICKEL GENUINE is another time-tested Hoyt alloy for use in gas and gasoline engines, automobile engines and marine engines of every class. Try it.

HOYT METAL COMPANY

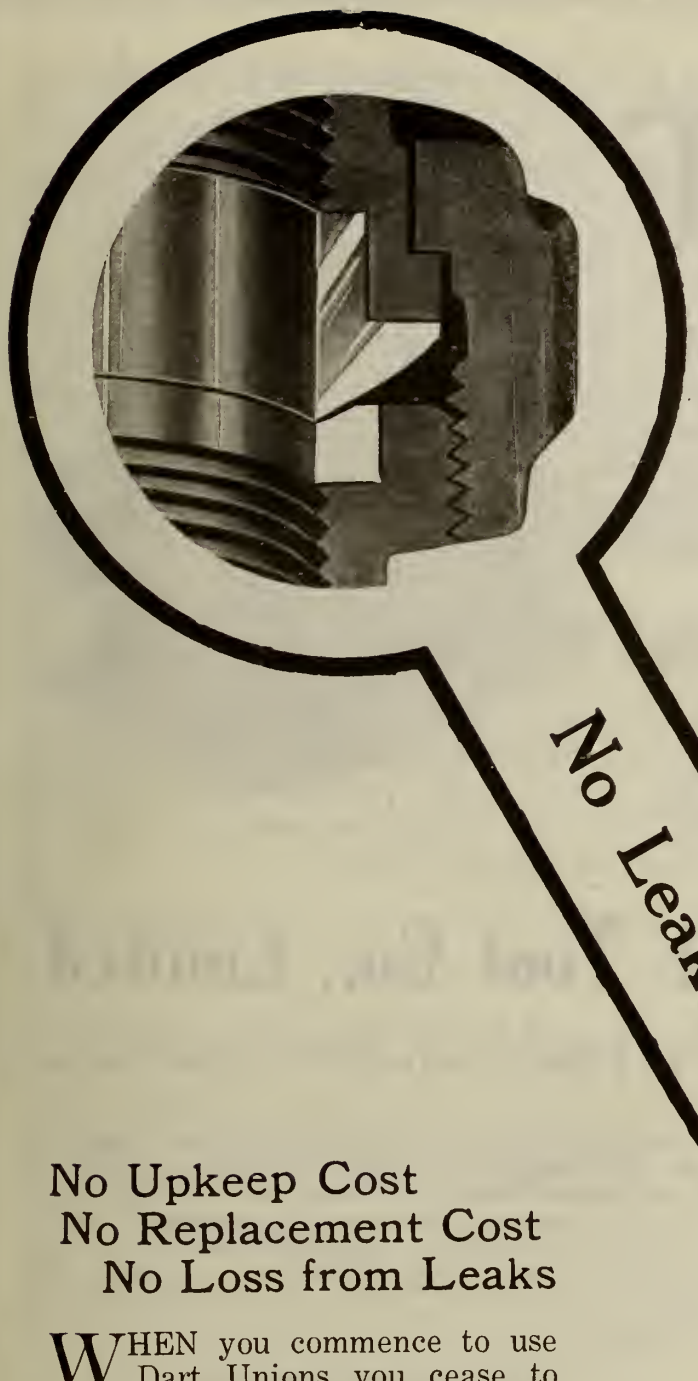
Power House, March, 1919, Vol. XII, No. 3. Published monthly at 143-153 University Ave., Toronto, Canada. Subscription price in Canada, $1.00; in United States, $1.50. Entered as second-class matter at the Post Office Department, Ottawa, Canada. Entered as second-class matter July 1, 1912, at the Post Office at Buffalo, under the Act of March 3rd, 1879.



DART UNIONS

Stay Tight

BRONZE meets Bronze at the Joint —this prevents deterioration.

Extra Heavy Iron Parts will not stretch, split or pull apart.

No Upkeep Cost
No Replacement Cost
No Loss from Leaks

WHEN you commence to use Dart Unions you cease to worry over couplings. Experience soon teaches you that "Bronze to Bronze at the Joint" means a permanently tight, sure joint that won't loosen up and leak. Furthermore you find that the ball-shaped seat allows for an easy connection regardless of the alignment of the pipe.

Order from your Jobber.

The

TALBOT

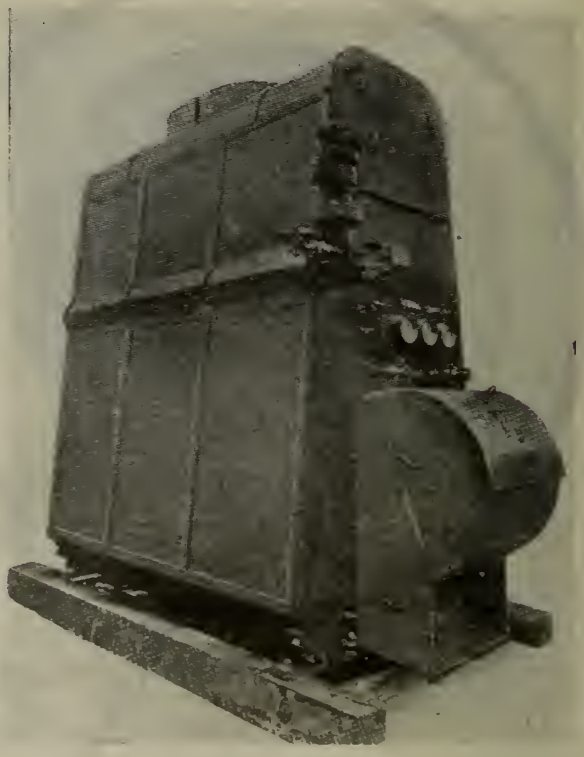
Contra-Flow Steam Boilers

(Equipped with Crude Oil Burners)

AND

Uni-Flow Engines

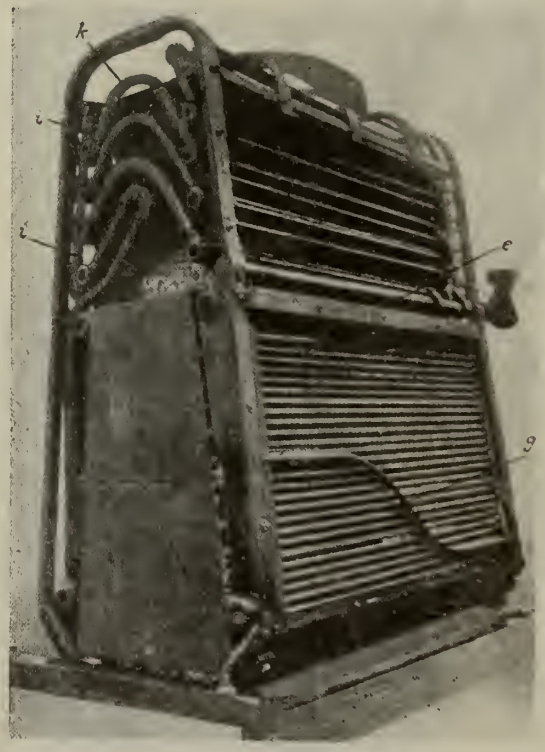
For Power Plants and Marine Requirement



Front of Boiler with Casing

Now Manufactured in Canada by the

Montreal General Tool Co., Limited



Rear of Boiler with Casing Removed

Write To-day for Full Particulars

The Talbot Contra-Flow Steam Boiler

The compact, lightweight, oil-burning Talbot Boiler has made the generation of steam so simple, **safe** and **cheap** that power plants and users of pleasure and commercial boats are able to obtain the **smooth-running, odorless** and **powerful** qualities of heavy-duty steam equipment, without boiler troubles, clutches, gears, fly wheels or danger. The boiler is non-explosive, and its control is automatic and positive.

The Uni-Flow Engine

The four-cylinder, double-acting, all-steel Talbot uni-flow engine is controlled by two small levers located in any part of the engine room of power plant or boat.

The reasons for economy are high efficiency of boiler and engine, low grade and cost of fuel, and the use of highly superheated steam, with no cylinder oil required.

A Steady Steam Pressure Plus

a saving of from 25 to 50% in Coal

The Jones Underfeed Stoker does this and more—

It saves much labor and gives you a smokeless stack.

Jones Underfeed Automatic Stoker

is remarkably simple, durable and efficient. No parts moving in contrast with the fire; no grates and no losses through bars.

Jones Underfeed Stoker Co., Ltd., 37-41 Britain St., Toronto

The Jones Stoker will greatly reduce your power costs. May we send you full particulars?

From Days To Hours

You can reduce the time required for repairing furnace linings or relining the furnace completely by using

REG. U.S. TRADE MARK PAT. OFF.

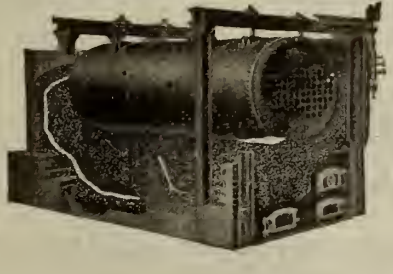
PLASTIC FIRE BRICK

It practically eliminates the risk of a shut-down and enables you to keep your boilers on the load.

Betson's saves you time, labor and trouble. There is no need to wait for shipments of special fire bricks or blocks or for experts to lay them.

What others are doing is good evidence. The largest industrial concerns who run their boiler plants continuously are using Batson's Plastic Fire Brick. Try out a barrel or two in repairs for your present fire brick lining. Then when the time comes for complete relining, you will certainly want to use Betson's for the job.

With Betson's Plastic Fire Brick any handy man can make a perfect, one-piece, jointless lining for any type of furnace or boiler, including front arch and wall, side-walls, bridge-wall, combustion chamber and back-arch, as well as baffles.



You can increase your general information on furnace lining practice by a study of our practical literature. Just ask for it.

When Buying Thermometers

There's Just Three Things to Remember—

First, you must have accuracy and sensitiveness—

Second, durability is absolutely essential—

Third, the thermometer must be suitably constructed for the intended application.

Accuracy, sensitiveness and durability are absolutely guaranteed in

"Crescent" Thermometers

And with nearly seventy years of experience to our credit, we are qualified to properly interpret your needs.

Our Catalog P.H. 200 illustrates and describes "Crescent" Thermometers for every application. Also test thermometers, glass thermometers, etc.

BOICO
WHAT A BARREL OF BOICO WILL DO
Put a barrel of Boico in your engine room and gradually feed it to your boilers and you'll have no more boiler side troubles. Boico solely attacks the scale. It eats thoroughly into the scale, loosens it and brings it away without doing the slightest damage to the boiler. Hardest and toughest of old scale formation succumb to the attack. One barrel will rid you of the worst formations. Then keep a barrel on tap, using a little of the cleanser each day to prevent new scale formations. Never injures boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming. Boiler scale wastes heat units —Boico will save you tons of coal. Try a barrel.

Another Coal Saver

Do you know a user of our **ANTI-CLINKER SHELL BAR GRATES?** Ask him of their merits. If you do not know a user, let us furnish you the name of one or more. You may then learn of their merits first hand. These grates assure perfect combustion. Result in more heat with less coal, and perfect clinker formations. Write for full details.

PLIBRICO---the one-piece Jointless Furnace Lining

PLIBRICO lasts longer than fire-brick, and it is easier to instal. If you want your furnaces to keep up the highest point of efficiency, use PLIBRICO. Let us tell you more about it.

TIP-IT---Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel. Investigate this modern process.

COPPUS TURBO BLOWERS EFFECT STEADY SAVINGS

In the modern plant of the New York Ice Company, New York City, this 22" COPPUS Turbo Blower has been saving time, money and labor ever since installation in April, 1917. It has **made possible** the use of cheap fuel, and **made sure** the maintenance of constant steam pressure. So satisfactory has been the service of this COPPUS Blower that two more blowers have since been purchased for other plants of the New York Ice Company.

COPPUS Turbo Blowers are cutting down fuel costs and keeping up steam pressures in cold storage and artificial ice plants all over the country. Automatically regulated, self-oiling, quiet-running—COPPUS Turbo Blowers are by far the most efficient means of securing mechanical draft.

Let our engineers tell you just what COPPUS Blowers can save you in your boiler room.

BRANCHES IN ALL PRINCIPAL CITIES

There is a FRICK Machine for every refrigerating purpose—all types: Vertical—Horizontal—Absorption.

Temptations

In these days of high prices, the temptation is often strong to put off repairs and improvements until the last minute, and then try to save money by purchasing materials cheaper in first cost but of doubtful efficiency. Either policy is liable to prove disappointing and costly in the end.

The time to get ready for next season's business is not when the hot weather is upon you, but right now when winter is relieving the load on your cold storage rooms. The sooner you make your repairs and improvements, the better. Materials are scarce and transportation is very uncertain at best.

And nowadays the best is still the cheapest. You can get cold storage insulating materials that will be cheaper than Nonpareil Corkboard in first cost, but in the long run—after they have become moisture-soaked, worthless as heat-insulators and have to be replaced—they are many times more expensive.

Fruit storage room insulated with Nonpareil Corkboard. Altschul Bros. Company, Lima, Ohio.

If you are not already familiar with it, there are many facts about Nonpareil Corkboard Insulation that will interest you as a business man. The 152 page, illustrated book and samples of the materials will be sent, free of charge, on request.

ARMSTRONG CORK & INSULATION CO.
504 McGILL BUILDING MONTREAL, QUEBEC, CANADA

AN UNBIASED OPINION

No matter how large nor how small the problem confronting you in connection with your Refrigerating requirements, our entire Organization is on the job to help you.

Sound advice in the beginning has saved many a firm and individual both time and money. We often learn something ourselves through these consultations, so we are always glad to help.

With our complete line of Ice-Making and Refrigerating Machinery, we are unbiased in our opinions. We fit the plant to your local conditions. We want every York Plant to stay sold and sell another.

List of customers, booklet, catalog, or information of any kind on the subject of Mechanical Refrigeration is yours for the asking without cost or obligation on your part.

Write us about your requirements and your inquiry will be referred to our Branch in your territory. The close personal touch is the best way to start any negotiation.

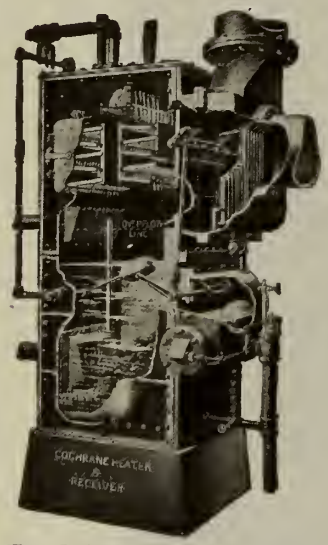
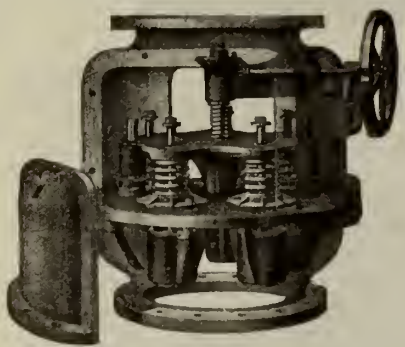
COCHRANE
COAL SAVERS



The Cochrane Open Feed Water Heater saves coal by utilizing exhaust steam to heat the feed water; 1% saving for each 11° F. rise.

The Sorge-Cochrane Hot Process Water Softener saves coal by heating the boiler feed water and by protecting the boilers against scale and corrosion.

The Cochrane Metering Heater saves coal by heating the feed water and helps save coal by telling whether or not the plant is being operated economically.



The Cochrane Multiport Back Pressure Valve saves coal by preventing leakage of exhaust steam and by making it easy to adjust the back pressure whenever desired. The Cochrane Oil Separator saves coal by rendering the exhaust steam useful for heating, drying and other purposes.

The Cochrane Oil Separator saves coal by rendering the exhaust steam useful for heating, drying and other purposes.

Canada Is Saving Many Thousand Tons
of Coal Per Year by Using Cochrane Heaters

Here are the figures:

The horsepower of Cochrane Heaters in use is about 10,000,000 boiler horsepower.

The corresponding amount of coal burned is 35,000,000 lb. per hour.

Considering an average of 10 hours' operation per day, 300 days per year (many heaters run 24 hours per day, 365 days per year), this amounts to 105,000,000,000 lb. of coal per year, or 50,000,000 tons, worth at $5.00 per ton, **$250,000,000.**

The saving due to the use of Cochrane Heaters is 1% to each 11° F. rise in temperature. On the average, the water is raised from 100° F. to 210 F. using steam at atmospheric pressure, 10% or a saving of 10%. Cochrane Heaters are thus saving about **$25,000,000** per year, which is vastly more than the heaters cost.

In addition, Cochrane Oil Separators are saving millions of tons of coal by **purifying exhaust steam** so that it can take the place of live steam in heating and drying coils, low-pressure turbines and industrial processes.

Sorge-Cochrane Hot Process Water Softeners are saving millions by **keeping scale and corrosive substances out of boilers** and thus saving expense and labor in cleaning boilers, and for new tubes and other boiler repairs.

Cochrane Metering Heaters are also telling hundreds of **steam-plant owners**, managers and operators **how much they are gaining in economy** by using different coals, different methods of firing, different methods of controlling the draft, stopping up air leaks in boiler settings, cleaning soot and scale from heating surface, etc. The total gains realized in this manner often amount to 25% or more.

Our engineering department has given hard study to fuel economy for over 25 years. It will be glad to aid you with suggestions if you will describe your present boiler feed water heating, softening, or metering arrangements, the amount of exhaust steam you have available and what you are using it for.

Ask for a book on "The Profitable Utilization of Exhaust Steam."

Setting a Candle to Catch a Thief

OUTSIDE air that filters through the brick-enclosing walls of boilers, costs industrial America many thousands of dollars each year because such leakage "cools" the fire, kills draft and therefore wastes coal to the extent of thousands of tons in the national aggregate.

Yet, just as the detection of such leaks is easy (see note under picture), so is the remedy simple; but it is simple largely through the pioneer work of Johns-Manville in its practical contributions to boiler-furnace improvement.

Through a complete line of products listed below, Johns-Manville can assure plants of new standards of heat saving in the boiler-room; standards that met and satisfied the Government during the coal crisis just past, when tons of fuel were saved and many hours of shut-downs averted—at a consequenc increase in factory production.

Seldom has conservation been better served by Johns-Manville than in this branch of its service.

And it can be predicted that the products listed below, and the expert knowledge of their application, will be of as great service to the nation in this present period of post-war readjustment as they were during the war.

Because to the progressive plant, conservation has become permanently a national obligation, as well as a business expedient.

CANADIAN JOHNS-MANVILLE CO., LIMITED
Montreal Toronto Vancouver Winnipeg Hamilton
London Ottawa

These Johns-Manville Products save fuel in boiler-rooms:
High Temperature (Refractory) *Cements* for boiler settings.
Aertite Boiler Wall Coating for boiler wall exteriors.
Monolithic Baffle Walls—tight, durable, easy to install; prevent short circuiting of hot gases.
Asbestos Sheets and Blocks for insulating hot surfaces; *Insulating Cements.*
Heat Insulations for steam and hot water piping.
Steam Traps.
Sea Ring Packing—eliminates unnecessary friction between rod or plunger and packing.

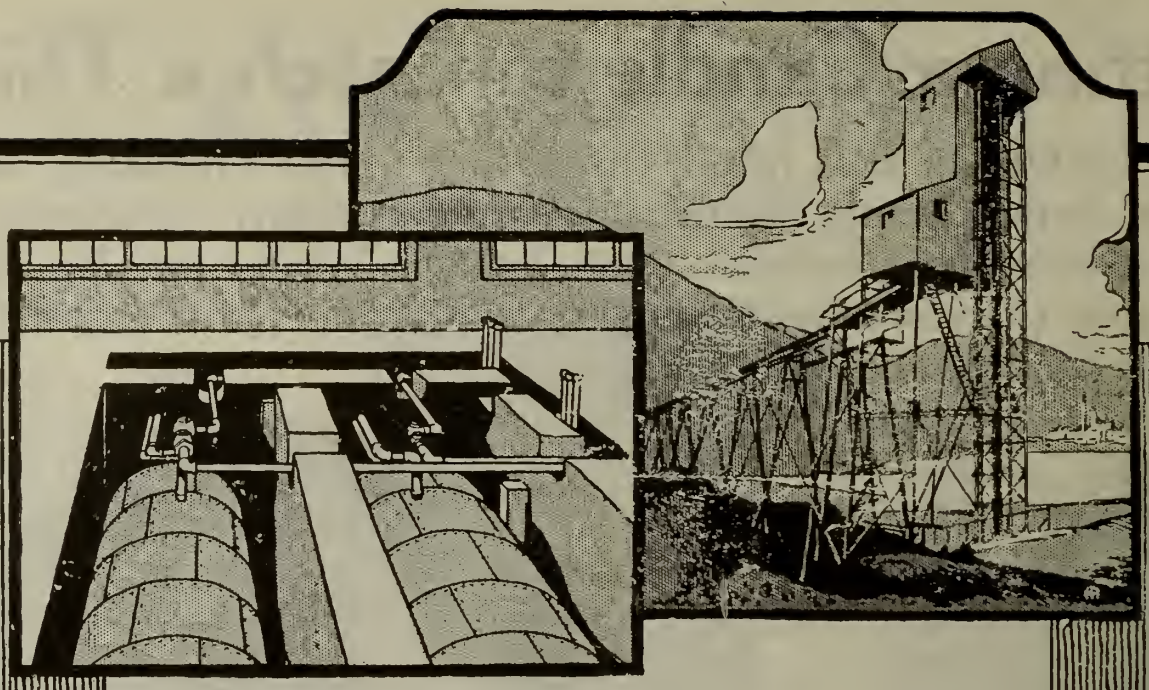
FIRE PREVENTION PRODUCTS

A WOODEN frame, over which is fastened a square of cardboard having a small aperture at its center, is pressed against a boiler wall and the edges temporarily but completely sealed by some plastic material. It is obvious that any leakage in the part of the boiler wall covered by this frame, will immediately be detected by the inrush of air at the small aperture in the center of the cardboard, consequently, a candle flame held to this aperture will be sucked inward, thus immediately revealing the fact that there is an infiltration of air through the boiler wall, which means fuel waste.

Thousands of tons of coal have been saved by preventing boiler wall leakage and by similar corrective measures at and around the boiler furnace.

A complete service in this department of engineering was one of the important contributions made by Johns-Manville during the fuel crisis.

JOHNS-MANVILLE
Serves in Conservation



Most Efficient and Convenient

IMPERIAL FUEL OIL ushers in a new era in steam generating. It is highly concentrated, easily stored in small space and burns without ashes, litter or cinders.

Every pound of Imperial Fuel Oil delivers the same number of B.T.U. With it there are no furnace doors to remain open and no grates or stoking devices needed. It is easy to obtain an efficiency of 85% with Imperial Fuel Oil. It is impossible to obtain an efficiency greater than 65% with coal. Very few firms obtain anywhere near this degree of efficiency with coal as fuel.

When convenience of handling and storage are considered, advantages of Imperial Fuel Oil are at once apparent. The labor it takes to deliver coal from the ground, under the boiler makes up a big percentage of its price. There is little labor attached to the handling of Imperial Fuel Oil. There is no shovelling on and off the cars, into storage bins and then again into furnaces. Imperial Fuel Oil can be stored in small space at any convenient point (under ground if desirable), and unlike coal, it will not deteriorate in storage.

Those interested in efficient steam power—all concerned with the heating of buildings and steam navigation—will find it worth while to investigate the merits of Imperial Fuel Oil.

The Imperial Engineers will gladly advise regarding Imperial Fuel Oil and the installation of any equipment that may be necessary in connection with its use.

Inquire at Room 704, Imperial Oil Building, 56 Church Street, Toronto, Ontario.

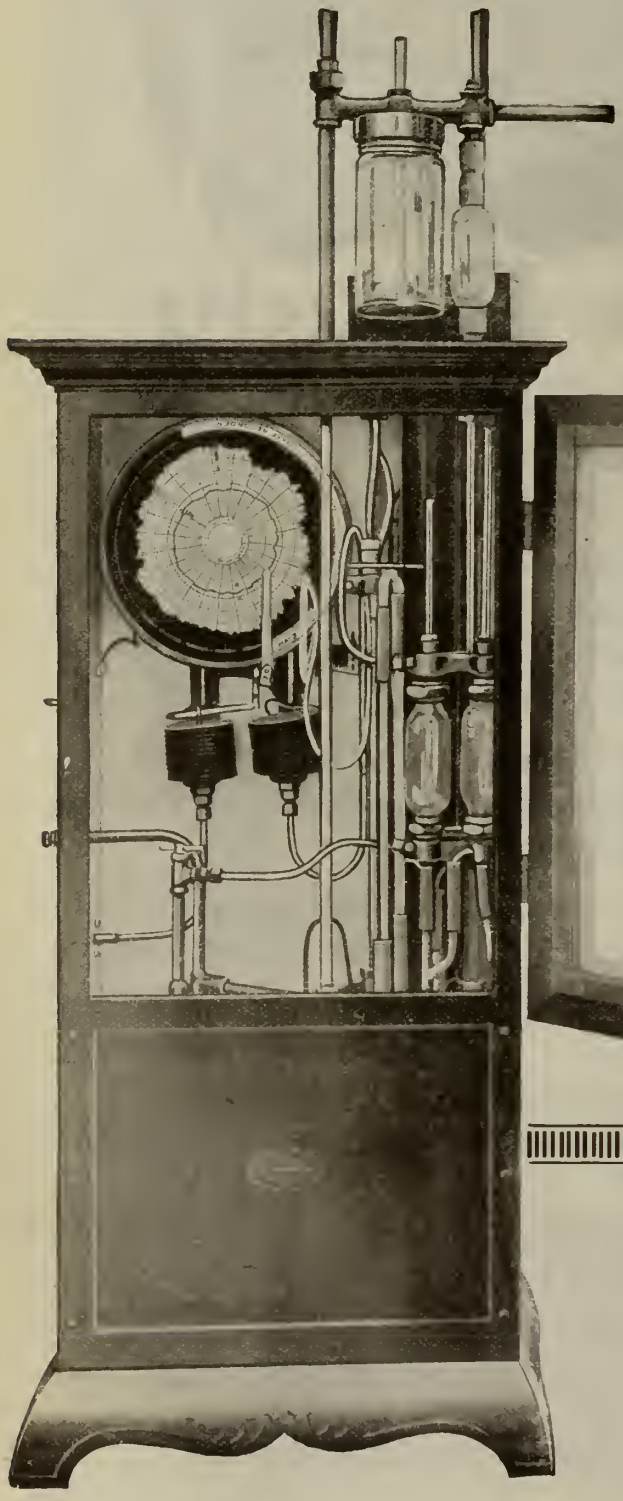
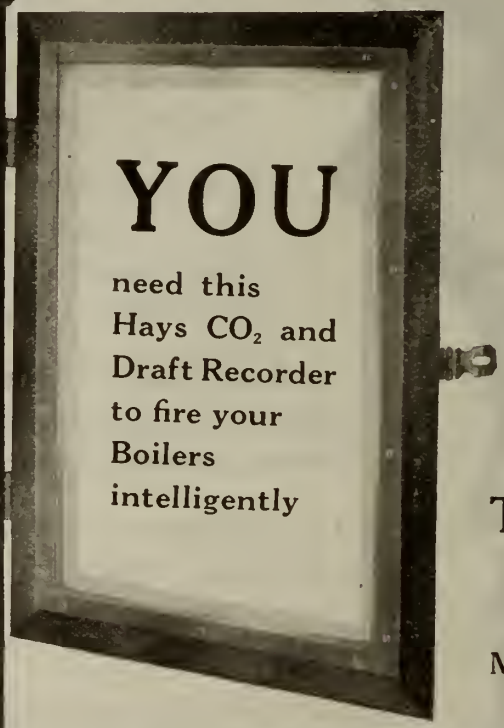
Hays CO_2 and Draft Recorder

Tells the Story of Boiler Efficiency

The exact reason why 30 to 50 per cent. more fuel is consumed in your plant than should be, is shown by the Hays CO_2 and Draft Recorder. With these appliances installed, your firemen can fire intelligently; they will work with accurate facts before them—instead of groping in the dark. For Hays CO_2 and Draft Recorder permanently record the story of efficient combustion



and Point Out Errors in *Firing, Draft, Boiler Settings, Etc.*



Hundreds of plants are using these Hays Appliances and saving 30 to 50 per cent. of their fuel expense as a result.

The Hays Recorder is automatic, self adjusting, infallible. It does not depend on hand adjustment and mechanical action for accurate operation. Indications are controlled by rising and falling columns of mercury, water and caustic potash.

We invite you to investigate, believing the facts will convince you that these Hays Appliances would quickly earn their cost in your plant.

Write for booklet "FUEL"

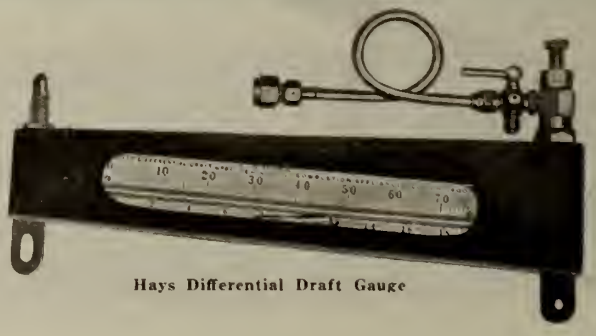
300 Hays Ave.

Michigan City, Indiana, U.S.A.



Hays Differential Draft Gauge

"See How That Thimble Locks Tight in the Side Bar"

In the Jeffrey Improved Carrier, a Steel Side Bar Chain with Double Bushed Joints is used.

Lugs in the steel side bars are locked tight to notches in both ends of the bushings confining all wear to the bushings which are readily renewable.

The two hardened steel bushings are assembled one within the other. The outer one is fixed to the inside bars and serves as a bearing for the chain roller. The inner bushing is fixed to the outside bar, and acts as a chain pin and receives the carrier cross rods.

Write for Catalog No. 210-4 describing in detail all the strong points of the Jeffrey Improved Carrier. Send for copy.

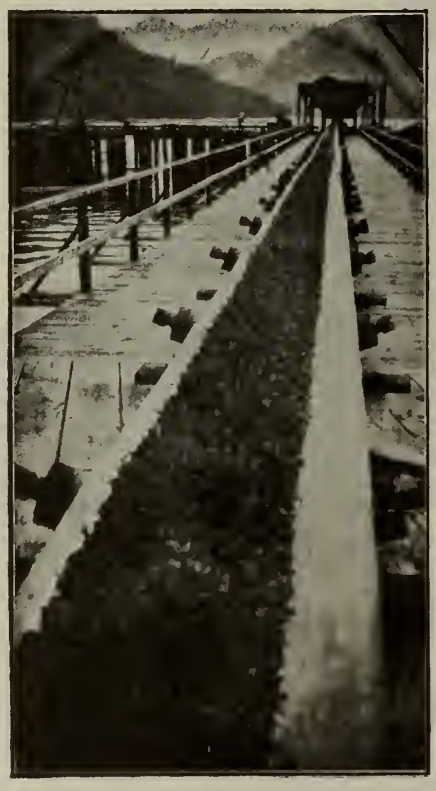
MONTREAL

Handle it Mechanically

Keeping Down the Cost of That Everyday Job of Conveying



FEW conveyor belts face extraordinary conditions, suffer extraordinary usage. It is on the everyday job—the steady grind—that a belt must make good to the last degree. Must give economical cost.

Take the Pacific Mills, Ocean Falls, B.C. Their conveyor job is to handle 45 tons of pea coal per hour over a distance of 476 feet. The conveyor runs level for 311 feet, and rises 30 feet in the remaining 165 feet. Motor 20 h.p. Head pulley 36 inches. Tail pulley 30 inches. Speed 285 feet per minute. Top rolls 6 feet apart. Return rolls 10 feet apart. Not a big belt problem. But a place where the conveyor belt must give long, economical service.

We recommend Goodyear Extra Duty Conveyor Belting *5 ply* with a 3-32 inch cover. This belt has a perfect service record up to the present—is still running and looks good for five years more service.

It is on just such jobs as this that Goodyear Conveyor Belting is winning the closest friends. If you have a conveyor drive on which costs are high, ask for a Goodyear belt man to advise with you. No obligation on your part. Phone, wire or write the nearest branch.

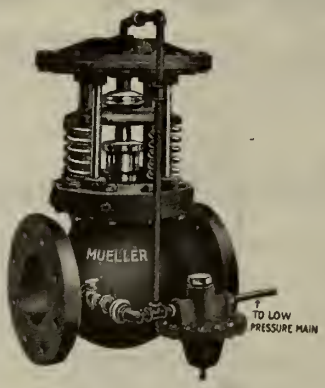
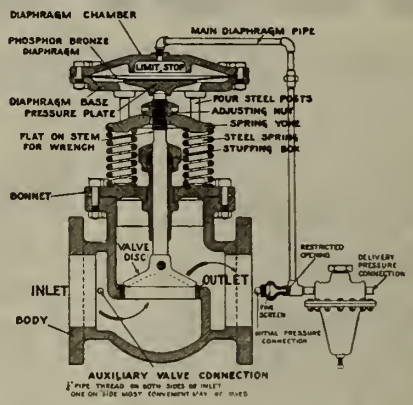
MUELLER Reducing and Regulating Valve

SINGLE SEAT; AUXILIARY OPERATED





E5030 for Water, Gas and Air
E5130 for Steam
(Flanged or Screwed)

Very Popular with Shipbuilders

USES

This valve is for use on exacting installations. It will make any desired reduction and will maintain a constant delivery pressure regardless of fluctuations of the initial pressure.

CONSTRUCTION OF STOCK REGULATORS

All valves have iron bodies, bronze stem and stuffing box, phosphor bronze diaphragms, seats of composition suitable for the required service; iron diaphragm chamber and steel springs. The main valve is controlled entirely by the small auxiliary valve. This auxiliary valve closes and opens the main valve by admitting initial pressure to, and releasing it from, the diaphragm chamber of the main valve according to the demand of the delivery side. Regulators of this description are suited for pressures up to 150 pounds, and will be furnished at above prices. When regulators are required for pressures in excess of 150 pounds we will furnish suitable material. Prices upon application.

STRAINER

In all cases it is advisable to use a strainer to prevent obstruction from grit, scale, cuttings, etc. Blow out pipes thoroughly before installing valve.

INFORMATION IN ORDERING

In ordering give highest and lowest initial pressure and required low or delivery pressure, approximate quantity or volume to be used per minute, size of high pressure pipe and low pressure pipe.

In ordering flanged end valves give diameter of flanges and bolt circles and the number and size of bolts.

INSTALLATION

Note—Any proper working regulator acts as a check valve. Where the building up of the pressure is to be avoided use our diaphragm operated relief valve E5060.

We will not be responsible for improper selection of valves.
Consult us regarding the best type for your service.

"The Mysterious German Onions"

On nights when the German air raiders were out, they sent up strange, luminous balls behind their lines and anchored them above the clouds—globes of fire which could be seen for forty miles or more. What these "onions" were, or how they were kept in stationary position above the clouds, is still a profound mystery. The Allies never learned anything about them, but the Allies night bombing crews steered their course to the Rhineland by the luminous buoys thus provided.

What is known about the onions is told by Lieut. J. Vernon McKenzie in the course of an article, "Raiding the Rhineland," in MARCH MACLEAN'S. It is an intensely interesting article, telling all about the great reprisal campaign which implanted the fear of war in the German civilian heart.

"NO HOPE FOR THE WETS"

"Already the temperance forces are lined up to stop any possible break in the prohibition dam," writes J. K. Munro, in discussing what is going to happen at the coming session at Ottawa. He predicts that Union Government will hold together, but that the habit it has contracted of promising everything asked is going to make a lively session. He expects:

Dry legislation at the earliest possible moment.
The moral reform forces in control.
No change in the Divorce Law.
Tariff concessions made to the West.

The March number, in fact, is full of live, up-to-the-minute features.
The famous Canadian Ace, Lieut.-Col. W. A. Bishop, is on the cover.

Some of the Outstanding Articles and Stories are:

The Transformation (a new serial)—By Frederic S. Isham.

A Canadian King-Maker (the story of Lord Beaverbrook in Britain)—By Maurice Woods.

Fitting in the Returned Soldier—By George Pearson.

The Three Sapphires—By W. A. Fraser.

The Strange Adventure of the Nile Green Roadster—By Arthur Stringer.

Fakers—and Others—By E. Ward Smith.

Lend Me Your Title—By Onoto Watanna.

A Shady Deal—By Archie P. McKishnie.

The City of Lost Laughter—By Mary Josephine Benson.

The Voice of Canada Interpreted

A new department starts in this number given over to summarizing and presenting opinion in Canada on outstanding topics, as reflected in the press. In this issue the department is given over to a careful compilation of opinion on the problems of the returned soldier.

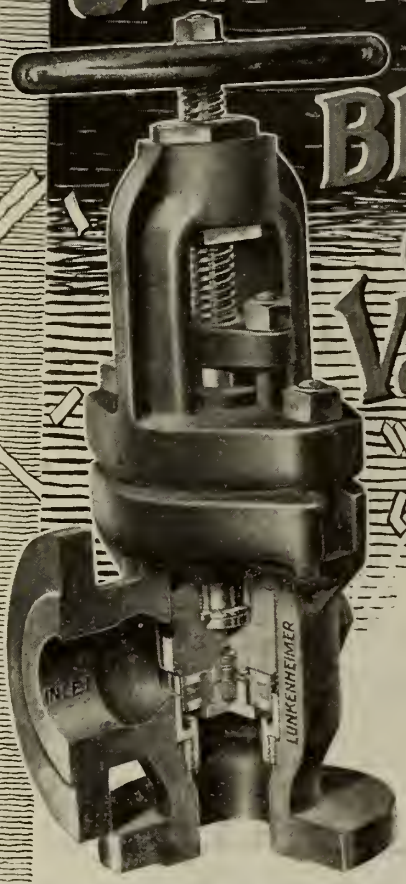
The ULTIMATE in Blow-off Valves



The "Duro" has demonstrated its peculiar adaptability as a blow-off by many years of satisfactory service, with a minimum cost for upkeep.

The self-cleansing seat feature prevents an accumulation of sediment on the seating faces during the blow-off, thereby reducing wear to a minimum and preventing leakage while the boiler is in operation.

To further enhance the durability of the valve, the disc is reversible; the disc face can easily be replaced with new material in case of wear, and all the parts, including the seat ring and reversible disc are renewable.

The materials and workmanship are of characteristic Lunkenheimer "Quality."

Specify **Lunkenheimer "Duro"** and insist on their installation.

BELT USERS!

Answer These Questions

If you have a belt drive that is giving trouble, if the belt is slipping, if power is being transmitted unsatisfactorily, or even if nothing is apparently wrong but you suspect that valuable power is being lost, answer these questions and let us assist you.

(1) What is the exact outside diameter of the driven pulley, inches?.....
(2) What is the exact outside diameter of the driving pulley, inches?.....
(3) What is the exact thickness of the belt in inches? .....
(4) How many revolutions does the driven pulley make per hour? Count accurately.....
(5) How many revolutions does the driving pulley make per hour? Count accurately.....
(6) What is the distance between shaft centers, feet? .....
(7) What kind of belt?.....
(8) What kind of pulley?.....
(9) What width of belt, inches?.....
(10) Is the belt running tight, medium or slack? .....

Upon investigation you will find that wherever Cling-Surface is "on the job" there are no belt troubles. Perhaps your belt needs Cling-Surface. Perhaps it doesn't. We cannot give correct advice without first knowing all conditions.

Cling-Surface frequently permits belts to be run real "slack." At least it permits the belts to run "easy." It does this because through that treatment the belt attains a natural pliability that causes it to hug the pulley closely through a greatly increased arc, making slip virtually impossible Besides it waterproofs the belt and makes it long-lived. It penetrates and surrounds every tiny fibre, eliminating internal as well as external wear.

You will find it worth while to know more about your belts, the total NUMBER OF MILES THEY SLIP PER YEAR, and the money wasted. So, if you will answer the above questions, we will tell you how much your main or other belt is slipping, and how much money you can save per year on that drive through Cling-Surface treatment.

Also, we have a valuable free trial offer that every belt user should know all about. Write for complete information.

Where an Ounce of Prevention is Worth a Pound of Cure

CLOGGED up condensers generally mean a shut down, a tremendous loss to the power user and the services of a crew of men for a considerable time in removing the debris and rubbish.

Link-Belt Traveling Water Screens insure a continuous flow of clear water to condensers and pumps. They remove and automatically dispose of all rubbish and trash before it can enter the intake. They operate just as effectively during floods as when water is at normal level. They reduce operating expense and increase the efficiency of your power producing equipment.

Our Book No. 305 describes our screens in detail and shows many installations. Send for a copy. If you will give us details of your intake conditions, our Engineers will gladly furnish recommendations and preliminary estimates for your particular needs.

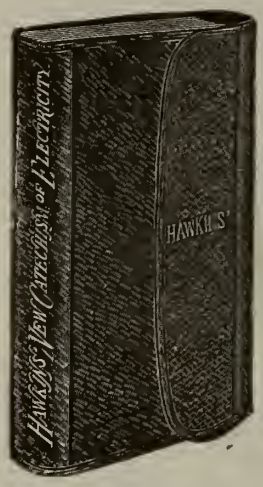
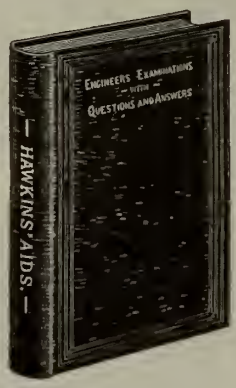
LINK-BELT
WATER SCREENS

Books for the Engineer's Library



Hawkins' New Catechism of Electricity

It contains 550 pages with 300 illustrations of electrical appliances; it is bound in heavy red leather, with full gold edges and is a most attractive handbook for electricians and engineers. One-third of the book is devoted to the explanation and illustrations of the dynamo, with particular directions relating to its care and management—$2.10 post paid.



Engineers' Examinations

By N. Hawkins, M.E.

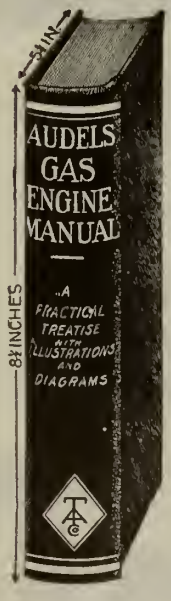
It presents in a condensed form the most approved practice in the care and managerment of steam boilers, engines, pumps, electrical and refrigerating machines with examples of how to work the problems relating to the safety valve, strength of boilers and horse power of the steam engine and steam boiler.—**$2.10 post paid.**

Steam Turbines

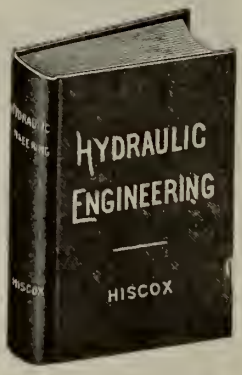
By Leland.

A reference work on the development, advantages and disadvantages of the steam turbine; the design, selection, operation and maintenance of steam turbine plants and turbo-generators. 135 pages. Illustrated.—$1.00.

Audel's Gas Engine Manual



A practical treatise relating to the theory and management of gas, gasoline and oil engines, including chapters on producer gas plants, marine motors and automobile engines.—$2.00.



Hydraulic Engineering

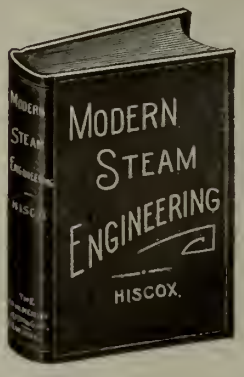
By G. D. Hiscox.

This comprehensive book of Hydraulics written by an experienced engineer, is a practical treatise on the properties, power and resources of water for all purposes, including the measurement of streams, the flow of water in pipes or conduits; the horse-power of falling water; turbine and impact water wheels; wave motors, etc. All who are interested in Water Works Development should have a copy. 320 pages, 305 illustrations. Price $4.15 post paid.

Compressed Air

By L. I. Wightman, E.E.

A reference work on the production, transmission and application of compressed air; the selection, operation and maintenance of compressed air machinery; and the design of air power plants. Illustrated.—$1.10.



Modern Steam Engineering in Theory and Practice

By Hiscox.

This book has been specially prepared for the use of the modern steam engineer, the technical students, and all who desire the latest and most reliable information on steam and steam boilers, the machinery of power, the steam turbine, electric power and lighting plants, etc. 450 pages. 400 detailed engravings.—$3.15 post paid.

Boiler Construction

By Kleinhans.

The only book showing how locomotive boilers are built in modern shops. Shows all types of boilers used; gives details of construction; practical facts, such as line of riveting punches and dies, work done per day, allowance for bending and flanging sheets and other data that means dollars to any railroad man. 421 pages, 324 illustrations, six folding plates.—$3.00.

Compressed Air, Its Production, Uses and Application. *By G. D. Hiscox, M.E.*

Comprising the physical properties of air from a vacuum to its liquid state, its thermodynamics, compression, transmission and uses as a motive power in the operation of stationary and portable machinery, in mining, air tools, air lifts, pumping of water, acids and oils and the numerous applicances in which compressed air is a most convenient and economical transmitter of power.—Price $5.15 post paid.

Boiler Accessories

By Walter S. Leland. S.B.

Assistant Professor of Naval Architecture, Mass. Institute of Technology, American Society Naval Architects and Marine Engineers. 144 pp., 80 illus. Cloth binding. A treatise giving complete descriptions of the various accessories of the boiler room and engine room essential to economical operation, such as evaporators, pumps, feed-water heaters, injectors, mechanical stokers, etc., with practical instruction in their use.—Price $1.10 post paid.

Garlock 1907 Combination Packing

Especially adapted for outside packed plungers of pumps handling extremely hot water. It is composed of Garlock Special Hydraulic, Diagonal and Cushion Centre Rings, which make it a strong and elastic packing, easy wearing on rods. There has been a long felt want for packing that would give satisfactory service on hot water rods and outside packed plungers, and this combination is the best known packing for that service. A trial will convince you.

Write for catalog describing our many styles and combinations of packing.

Insurance Against Shutdowns—

JEFFERSON UNIONS

Backing up the engineer in his effort to boost production to top-notch records you'll find JEFFERSON UNIONS. Big production requires steady, uninterrupted service, steam lines that carry great variations in the load and air lines that deliver full pressure under all conditions of service.

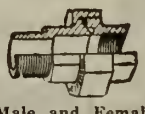
JEFFERSON UNIONS are to-day, as in the past, meeting exactly every requirement of severe service. They are constructed extra heavy of the highest quality materials—a feature that insures the continuous perfect service so essential in the power plant.

Be sure to get JEFFERSON—the name on the nut protects you from the "just-as-good" variety and costly break-downs.

Ask your jobber to show you JEFFERSON Unions to point out where they are different. Our new Catalog, "UNIONS," describes the complete JEFFERSON LINE. Write to-day for your copy.

Ask Your Jobber About These Jefferson Specials

Union Tee, with union on the outlet. Made also with male end on outlet.



Male and Female Union. Does away with a nipple, and makes a short connection.

Union Elbow with 45° angle. Also made male and female.

JEFFERSON UNION COMPANY

Lexington, Mass.

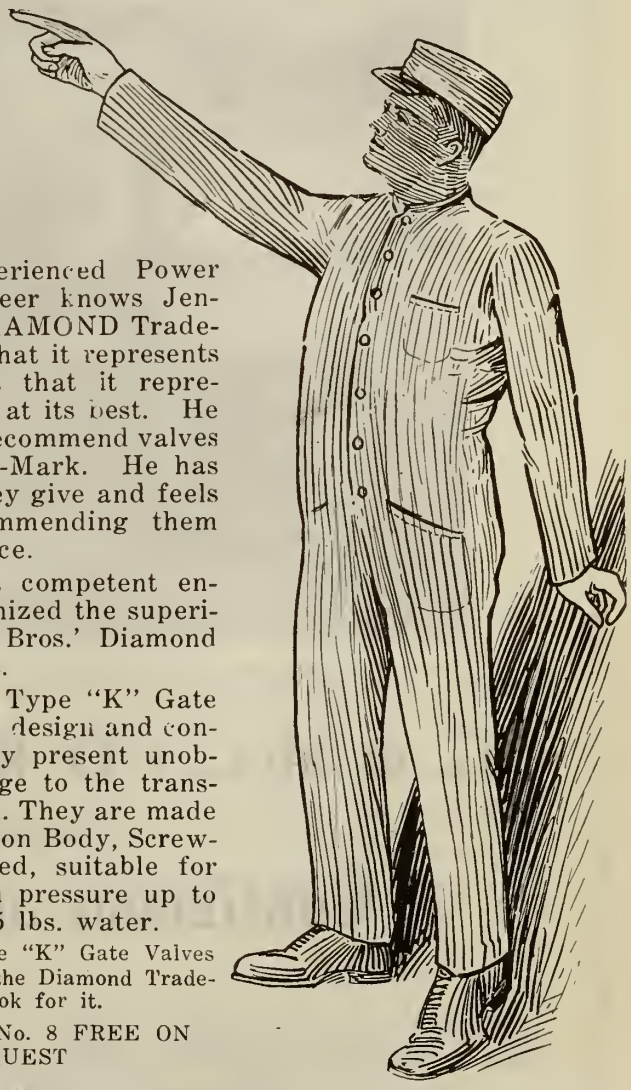
TRADE JENKINS MARK

Type "K" Brass and Iron Body Gate Valves

Appreciated by Men Who Know!



EVERY experienced Power House Engineer knows Jenkins Bros.' DIAMOND Trade-Mark—he knows that it represents quality—he knows that it represents valve service at its best. He never hesitates to recommend valves bearing this Trade-Mark. He has seen the service they give and feels confident of recommending them for any valve service.

For over 50 years competent engineers have recognized the superiority of Jenkins Bros.' Diamond Trade-Mark Valves.

Jenkins Bros.' Type "K" Gate Valves excel in design and construction. They present unobstructed passage to the transmitted medium. They are made in Brass and Iron Body, Screwed and Flanged, suitable for working steam pressure up to 125 lbs. or 175 lbs. water.

All Genuine Type "K" Gate Valves are identified by the Diamond Trade-mark. Always look for it.

POWER HOUSE

Established 1907 Published Semi-monthly

Power House to Be Issued Twice a Month

SUCCESS comes to him who earns it and opportunity takes care to knock at those doors already ajar. Preparation for success calls for study, for investment in skill and patience. The man who achieves success has done so through his own hard work and through his ability to use the experience of others to his own advantage. One of the greatest assets an engineer can acquire is the knowledge that comes to him from the reading of good books and the technical press.

Our opportunities for service in this respect will be doubled by a change made with the coming issue. POWER HOUSE will now be published semi-monthly, a step that has been urged by our readers for some time.

The trade paper is successful only to the extent to which it is a power for education and self-improvement. In the coming months our facilities for serving the engineering field will be doubled and the several branches of power plant engineering will receive the attention they all merit.

The field of power plant engineering has developed immensely of late years and the competent engineer has not only to be well versed in the science of steam engineering but has to be familiar with the design and operation of electrical apparatus. This is particularly true in Canada where water powers are so plentiful and coal, in some localities, scarce. Not only is this true, but the smaller power plants of manufacturing industries in almost every case are supplied with motive power from an outside station or use electricity for the shop transmission of power, in some degree. In meeting the need for educational opportunity along this line we have greatly strengthened the electrical section of POWER HOUSE, and during the coming year will cover the practical side of electrical engineering in a very thorough manner with the aid of several contributors of recognized standing. The more advanced and theoretical side of this branch of science will also be ably dealt with.

The operation of the modern steam plant is becoming more complex and greater attention is being given to its economical operation. The present trend in plant design towards higher steam pressures, the use of the turbine, increasingly evident in the smaller sizes of power units, the more efficient engines being installed to-day and the enormous strides taken towards greater efficiency in the boiler room all necessitate more knowledge on the part of the operating engineer.

As in the past, this phase of power plant engineering will be made one of the strongest editorial features.

The internal combustion engine is rapidly assuming a place in the generation of power that its economical and simple operating characteristics deserve, and articles will appear from time to time on the latest developments of this prime mover.

Mention has been made of Canada's abundant water-powers. A number of articles are in the course of preparation dealing with some of the more interesting developments which have taken place in this field.

The other departments, refrigeration, hydraulics, our new equipment pages and all will increase in usefulness in direct proportion to the increase in space available for their appearance.

In addition to the above features, our regular departments will also gain through our more frequent publication. And in particular those departments dealing with new power plant equipment, questions and answers and the operators' point of view will be greatly strengthened and will be of still greater value to the engineer in consequence.

The Utilization of Solar Energy

A Review of Some of the Attempts That Have Been Made to Utilize Directly the Sun's Heat and an Indication as to What May Be Accomplished in the Future

By J. F. HEFFRON

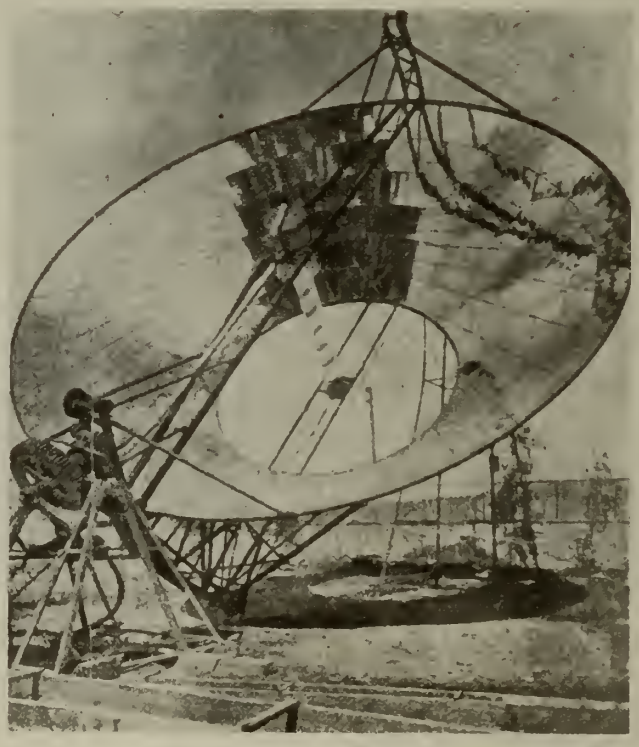
IN writing on this subject, it will no doubt interest the readers if a few observations are made regarding the principal factor in all schemes for the utilization of solar energy, viz., the sun.

Since the sun is presumably the source of all our earthly energy and heat, and man could not exist without its beneficient radiation, we can well understand that speculation regarding its qualities and constitution has ever attracted the attention of physicists, and we are not surprised that several intelligent and cultured races, such as the ancient Indians, Mexicans and Peruvians, directed their prayers to it, and looked upon it as one of the gods.

Some years ago a French artist of great imaginative power painted an extraordinary picture called "The Last Man and Woman." Two skeletons, huddled together in a close embrace, crouched in a weird icy cavern, from whose roof huge icicles depended, while the walls and floors glistened in set glossiness—the last human couple frozen to death. The painting left a deep impression on all who saw it. It was a pictorial representation of the now discredited theory that the earth must steadily grow colder in consequence of a decrease in solar heat, and that the last generation of mankind will perish of cold at the equator as a tribe of Eskimo.

Truly a ghastly outlook for the human race. But fortunately, later theories do not permit us to longer regard the sun as a monster fire, burning in the manner of fires in our grates. Tremendous as is the sun's mass, it would be comparatively rapidly consumed if such combustion were taking place. Another reason for discarding this old idea is that the temperature of the sun has been determined by a number of experimenters; all agree that it is about 6.000 degrees C. This temperature is far too high to permit of the formation of most chemical compounds, and for the production of heat by combustion, it is necessary that such compounds be formed. Briefly, such a temperature decomposes nearly all compounds into their elements and prevents their reuniting and the consequent production of heat.

Scientists are by no means certain how the sun's heat is produced, but one theory is that it is due to radioactivity; and another, due to Helmholtz, that the energy to keep up the radiation could be supplied by a relatively microscopic contraction of the sun's volume, though even this theory is not a complete success, as it implies that the age of the sun is 17,000,000 years. Great as is this lapse of time, geology indicates that our earth is considerably older; but as the earth can not very well be older than the sun, we must conclude that the sun is older than 17,000,000 years.



—From Smithsonian Report, 1915
FIG. 1—THE PASADENA SUN-HEAT ABSORBER OF 1901

As to what constitutes the structure of the sun there is also doubt; but the inner portion is spoken of as the nucleus and the outer portion as the atmosphere, and as the outer layers of the atmosphere become relatively cooled in rising from the surface of the nucleus, they sink back to a lower level, and their place is taken by hotter layers. Thus there is a continual circulation of the sun's atmosphere.

The specific gravity of the sun is only about a quarter of that of the earth, whose specific gravity is 5.53. A cubic foot of water weighs 62½ pounds, and hence an average cubic foot of the sun weighs 86¼ pounds, while an average cubic foot of the earth weighs 345 pounds. For comparison it may be mentioned that a cubic foot of granite weighs 165 pounds. The density of the sun being so small, it is concluded that it can still go on contracting, and hence that it is probably getting hotter instead of cooler, as is popularly supposed. If this be true, it is a hopeful feature for future workers in the field of solar energy.

The diameter of the sun is 863,600 miles, or about one hundred times the diameter of the earth. The glowing surface which the sun presents to us, even considering it as a flat disk, has the enormous area of 585,753,000,000 square miles, each square foot of which emits the enormous amount of about 12,500 h.p., and the radiant energy received at the outer surface of the earth's atmosphere is equivalent to 7,300 h.p., per acre. Of this about 70 per cent. (about 5,000 h.p. per acre) is transmitted to the land surface of the earth at noon on a clear day, and less in the morning and evening, owing to the greater thickess of the atmosphere through which the radiation has to pass at these times.

The quantity of solar heat per unit area which arrives in unit time at the outer surface of our atmosphere is called the solar constant, and its value, as determined in 1913 by C. G. Abbot, after making 696 experiments in different parts of the globe, is 1.93 calories per square centimeter per minute, which equals 7.12 B.t.u. per square foot per minute.

Perhaps the most remarkable things about solar radiation are that it passes without change through the 93,000,000 miles of space between the sun and the earth, the temperature of which is nearly absolute zero, and that only three-fifths of it produces any impression on the human eye. It is not till the radiant energy impinges on some material body that it is converted into heat. The best body for causing such conversion is a dead black one.

The absorption of solar energy by the atmosphere is about 20 per cent. greater in summer than in winter. This may be due to there being a larger total quantity of water vapor in the atmosphere of the earth in summer than in winter. It has long been known that the greater the humidity of the atmosphere the greater the amount of heat intercepted by it.

Although the theoretical power value of the heat reaching the surface of the

earth is no less than 5,000 h.p. per acre, it must not be thought that anything like this amount can be converted into mechanical power any more than can all the heat of coal be converted into its theoretical equivalent of mechanical power. For example, the heat value of good coal is about 14,500 B.t.u. per

—From Smithsonian Report, 1915
FIG. 2—ADAMS' SOLAR COOKER, 1876

pound, equal to 12,760 h.p. hours per ton, but in fact the best result, even under test conditions, ever obtained from a ton of coal by means of a boiler and steam engine is only about 1,470 brake h.p. hours, or 11.5 per cent. of the heat value, while in the case of a gas engine the corresponding figure is 25.5 per cent., and of a Diesel oil engine 31 per cent. The chief loss is in converting the steam into mechanical energy, and most of the loss is inevitable for thermodynamic reasons. With this fact in mind, one is not surprised to learn that the best overall thermal efficiency obtained from the most modern sun power plant, the Shuman-Boys plant (Fig. 1) in Egypt was only 4.32 per cent., the chief reasons for this being that the steam pressure was so low, and that the highest efficiency of the sun-heat absorber was only 40.1 per cent., compared with 75 per cent. for the best coal-fired boiler. But it has taken boilermakers many years to attain this efficiency, so that 40.1 per cent. is not a bad result when the number of sun boilers that have been made is taken into account.

Thermal efficiencies of engines are materially affected by the heat fall of the steam, just as the effciencies of water turbines are affected by the height of the waterfall. The greater the fall in either case the better the efficiency.

It will be interesting to learn from the foregoing figures that the value of 2½ acres of bright sunshine for an hour is one ton of coal. Mr. J. C. Hawkshaw in his address to the Institution of Civil Engineers (London, 1902), pointed out that the wood fuel produced by an acre of land in Europe is equivalent to at least one ton of coal a year. The great possibilities that lie in the utilization of solar energy, and the obvious fact that there is a limit to our supplies of coal and oil, have naturally attracted a number of workers, the results obtained by some of these savants dating back as far as the fifteenth century.

Sun Power Plants

Having given some consideration to the nature of the source and to the quantity of heat available, we may now direct our attention briefly to a description of some of the plants that have been constructed by various experiments for the purpose of utilizing solar heat.

Perhaps Buffon, the celebrated French naturalist, was one of the earliest workers in this field whose work resulted in any measure of success. On April 10, 1747, he succeeded, we are told, in setting fire to a plank of tarred wood, at a distance of 150 feet, by solar rays reflected from a combination of flat mirrors. He did this to show the possibility of the legend that Archimedes set fire to the fleet of Marcellus at Syracuse in 212 B.C.

Other early workers were Roger Bacon, an English Franciscan monk, who died in 1294; Solomon de Coux (1576-1626), a French engineer, who, in 1615, invented and described the first machine for raising water by solar heat and the expansion of air; Ducarla; and H.B. de Saussure, the Swiss geologist, physicist, and naturalist, who made (in 1787) the second ascent of Mont Blanc, a great feat in those early days. To de Saussure the credit is due for inventing what is known as the "hot box" (i.e., an insulated air-tight wooden box, black inside, and covered with two layers of clear glass with an air space between them) which has since been such a favorite with other workers. It was he, too, who found that a cover of two sheets of glass gave the best results.

Next in the field was the great English astronomer, Sir John Herschel, who experimented with a "small mahogany box, blackened inside, covered with window glass fitted to size, but without putty, and simply exposed perpendicularly to the sun's rays." He recorded the temperature of the surface soil near Cape Town, South Africa, obtaining a temperature of 240.5 degrees F.

As this temperature far surpassed that of boiling water Sir John made some amusing experiments by exposing eggs, fruit, meat, etc., in the box, all of which he tells us in his report, after a short exposure, were found perfectly cooked, and were eaten with relish by the entertained bystanders.

In 1873 Carl Guntner of Laibach exhibited a reflector intended for use in gathering solar energy at the Vienna Exposition. It was made of sheet metal and possessed the disadvantages common to all sheet-metal reflectors—that to maintain the surface in proper condition when exposed to all sorts of weather, requires careful and costly attention.

The work of the French scientist August Mouchot in this field was certainly of great importance. His experiments are recorded in his book entitled "La Chaleur solaire et les Applications industrielles," 1879; but, as with other early workers he gives extremely meager information of the results obtained.

Mouchot started his solar work in 1860 and took out his first patent in 1861. In the first edition of his above-named work he stated that theoretically, on an average, 86 square feet of reflecting surface are required for 1 h.p. Then to allow for losses, he doubled the area, thus making it 172 square feet. It is to be noted he referred to reflecting surface, not the area of radiation collected, which would almost certainly be a smaller quantity.

In August, 1866, Emperor Napoleon III. of France saw Mouchot's first solar engine at work in Paris. It consisted of two cylindrical concentric copper vessels with domed tops, the water space to accommodate 3½ pints being between them. The boiler was covered by a bell glass and placed at the focus of a reflector. The water boiled in one hour from an initial temperature of 50 degrees F.

—From Smithsonian Report, 1915

FIG. 3—GENERAL VIEW FROM THE SOUTH OF THE SHUMAN-BOYS ABSORBER, MEADI, 1913

After interesting the Emperor, Mouchot received some monetary assistance from the French Government with which he constructed another sun boiler, along the lines of the original one, but larger. This boiler was able to raise steam to 75 pounds to the square inch, and was found capable of running an engine which made 80 strokes per minute under a continued pressure of 1 atmosphere. Later it was changed for an engine with a revolving cylinder,

which worked admirably, putting in motion a pump to raise water, until the pump, which was too weak, was broken.

Next came the versatile engineer and successful inventor, John Ericsson, a Swede by birth and an American by adoption. He made an immense number of experiments, extending over twenty years, with costly apparatus, to determine the solar constant, and later on made apparatus for the practical utilization of solar radiation. All these experiments were made at his own expense, and he tells us they cost him $100,000. The conclusion he arrived at, as given in one of his letters, is that: "Although the heat is obtained for nothing, so expensive, costly, and complex is the concentration apparatus, that solar steam is many times more costly than steam produced by burning coal."

From Smithsonian Report, 1915

FIG. 4—GENERAL VIEW FROM THE WEST OF SHUMAN ABSORBER, TACONY, 1911

W. Adams, deputy registrar, High Court, Bombay, seems to be the sole Englishman who has worked on the practical side of the problem. His work was done in India, and is recorded in his interesting book, Solar Heat (Bombay, 1878).

In two particulars Adams was much at fault. He believed that the solar rays reaching the earth are not practically parallel, in spite of the opposing opinions of the many physicists he quotes. He erred also in believing that the temperature attained at the focus of a lens or mirror is directly proportional to the concentration of the rays. As a consequence, he stated that if a lens 85 feet 4 inches in diameter concentrated the radiation onto a circle one-half inch in diameter the temperature would be 73,400,320 degrees F. This is equal to 40,780,000 degrees C., while the temperature of the sun itself is only 6,000 degrees C., and no amount of such concentration could produce a temperature in excess of this. This error on the part of Adams seems to be due to a confusion of "temperature" with "quantity of heat." Adams constructed several fairly large solar machines, with which he obtained very satisfactory results, his last machine being able to operate a steam pump of 2½ h.p.

He also constructed a solar cooker, which was a miniature of his larger machines (see Fig. 2). The reflecting portion of the machine was formed of eight sheets of plane glass arranged to form a hollow truncated octagonal pyramid 2 feet 4 inches in diameter at the larger end. The food was placed in a cylindrical copper vessel at the axis. With this apparatus, he and others cooked many meals, both stews and roasts, which it is stated were very palatable.

Adams supported the opinion also that the ancients knew something of the utilization of solar energy for the creation of fire. He states:

"When the sacred fire that burned in the Temple of Vesta (The Goddess of the Hearth) became extinct, the ancient Romans used to rekindle it by placing a piece of dry wood in the linear focus of the conical reflector. . . . . To bring fire from heaven, by supernatural aid and a metal reflector was, no doubt, one of the most ancient miracles of priestcraft."

Adams suggested many practical uses for solar heat, curiously, among others, "for the cremation of deceased Hindus and others."

After Adams, M. Abel Pifre, a Frenchman, attacked the problem but the claims for efficiency in the case of his machine are quite improbable, in the face of later experience.

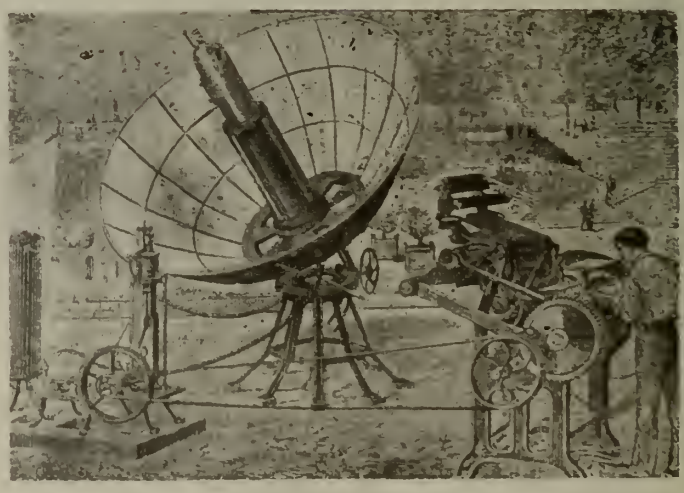
The next noted experimenter was a native of this continent—Langley, the American. His work consisted of many experiments to determine the value of the solar constant, which he gave as 3 calories per square—centimeter—minute.

Next may be noted a plant erected at Salinas, Chile, 4,300 feet above sea level, by J. Harding, for the purpose of distilling water by solar radiation. His plant had 51,200 square feet of glass arranged in sections 4 feet wide, in the form of a very flat inverted V, forming the roof of a shallow water trough. The sun evaporated the water, the resulting vapor condensed on the glass, the temperature in the box being far higher than that of the atmosphere, and hence of the glass. The pure water trickled down the sloping glass and dripped from its lower edge into a small channel on the top of each side of the box. These channels delivered into larger ones, and thus the distilled water was collected. The plant yielded 5,000 gallons of pure water per day in summer, and allowing for interest on capital, upkeep, etc., the cost of the pure water is said to have been less than one-half cent per gallon.

In the United States in late years several sun power plants have been erected, perhaps the most popular of these was that located at Pasadena in 1901. (See Fig. 1). It consisted of a truncated cone reflector, 33 feet 6 inches in diameter at the larger end and 15 feet in diameter at the smaller, with a boiler 13 feet 6 inches long, having a capacity of 100 gallons (U.S.A.) plus 8 cubic feet of steam space.

The all-day average work performed by the engine is given as 1,400 gallons (U.S.A.) of water lifted 12 feet per minute, which is the rate of 4¼ h.p.

The Pasadena plant is said to have cost $5,000 and in 1909 it was perhaps the largest and strongest of the mirror type of solar motor ever built.



From Smithsonian Report, 1913

FIG. 5—PIFRES SUN-POWER PLANT OF 1878, DRIVING A PRINTING PRESS.

H. E. Willsie and John Boyle, jr., started their work in America in 1902. The method they adopted was to let the solar radiation pass through glass and heat water, which in turn was used to vaporize some volatile fluid such as ammonium hydrate, ether, or sulphur di-

oxide, the vapor being used to drive an engine.

Willsie has stated that he believes himself to be the first to propose this two fluid method for the utilization of solar energy, and so far as is known, his claim is correct. Several sun-heat absorbers were successfully built in the United States after this method, and in 1903 patent applications were filed, and later a company known as the Willsie Sun Power Co. was incorporated.

In the spring of 1904 a plant was built by Willsie at St. Louis, which successfully operated, by ammonia, a 6 h.p. engine. Later a similar plant using sulphur dioxide, was built at The Needles, Col. Its results caused Willsie to construct a larger plan which obtained boiler pressures of over 200 pounds, and the engine operated a centrifugal pump, lifting water from a well 43 feet deep (sic) and also a compressor, in addition to two circulating pumps.

A fourth plant, along the lines of the last, was later constructed along the Colorado river which gave equally good results.

In 1907 Frank Shuman, an American, had a plant in operation which developed 3½ h.p. 1,200 square feet of sunshine fell upon a fixed, horizontal water box with a glass top. In the water were rows of parallel horizontal block pipes containing ether, and exposing 900 square feet of surface to the solar radiation. The water became heated and conveyed heat to the under side of the pipes. The ether boiled, and its "steam" drove a small vertical, single-cylinder engine. The exhaust ether vapor passed into an air surface condenser, and the liquid ether from this was pumped back into the tubes of the boiler already described.

Shuman states that this plan ran well even when snow was lying on the ground. At first thought this seems remarkable, but though in winter the number of solar rays falling on a given horizontal area is smaller than in summer, the permeability of the atmosphere is about 20 per cent. greater in winter than in summer, which counteracts the other effect, but of course the loss of heat by conduction from the boiler is greater in winter than in summer.

Shuman later made other experiments and in 1911, with the assistance of some English capitalists, constructed his third absorber at Tacony (a suburb of Philadelphia). The total quantity of solar radiation collected by this apparatus was many times larger than that collected by any previous worker, the total area being 10,296 square feet. In the best run of one hour this plant produced 816 pounds of steam at atmospheric pressure. This is at the rate of 9 pounds per 100 square feet of sunshine, and therefore equivalent to an allowance of 2.45 square feet of sunshine per brake h.p. The maximum thermal efficiency of this absorber was 29.5 per cent.

In 1911 at the request of the Sun Power Co. (Eastern Hemisphere), (Ltd), their consulting engineers (Messrs. A. S. E. Ackermann and C. T. Walrond invited Prof. C. V. Boys, F.R.S., to become associated with the solar radiation work they were carrying on. Prof. Boys suggested some changes in the design of the absorber, viz., that the boilers should be placed on edge in a channel-shaped reflector of parabolic cross section, so that solar radiation was received on both their surfaces, instead of one being worse than idle, as it was when the boilers were placed side on the sun. This design, which is similar to that used by Ericsson, was adopted.

An absorber of this design was then constructed and erected at Meadi on the Nile, 7 miles south of Cairo, in 1912, (See Fig 3). The axis of the reflectors was placed north and south, and could be automatically heeled over from an eastern aspect in the morning to a western one in the evening, so as to follow the sun. Thus the same number of solar rays were caught during the entire day, a small decrease in steam production in the morning and evening being entirely due to the greater thickness of atmosphere through which the rays had to pass at these times. The total area of sunshine collected was 13,269 square feet.

The boilers were placed at the focus of the reflectors and were covered with a single layer of glass inclosing an air space around the boilers. Each channel-shaped reflector and its boiler was 205 feet long, and there were five such sections placed side by side. The concentration was 4½ to 1. The maximum quantity of steam produced was 12 pounds per 100 square feet of sunshine, equivalent to 183 square feet per brake h.p., the maximum thermal efficiency was 40.1 per cent. The best hour's run—Mr. Ackermann tells us in his report to the Royal Society of Arts, (London)—gave 1,442 pounds of steam at atmospheric pressure, hence, allowing the 22 pounds of steam per brake h.p.—a result about 10 times as large as any previously attained, and equal to 63 brake h.p., per acre of land occupied by the plant.

In spite of this review of comparative failures, most scientific men who have given this problem their serious consideration are of the opinion that it is well worthy of the attention of engineers, for even now it is very nearly a solved problem where there is plenty of sunshine and coal costs over $20.00 a ton. It is fortunate, Mr. Ackermann observes, that where coal is dear sunshine is often plentiful, and while coal will no doubt gradually increase in price, the cost of sun-power plants should decrease. Sun-power plants are admirably suitable for pumping in connection with irrigation, for where there is most sunshine there is great need for irrigation, and the slight variation in the quantity of water pumped throughout the day does not matter.

These plants are at present costly to build, involving the erection of expensive equipment, which so far is uneconomical in working, utilizing but a small fraction of the available sun energy. We may however not unreasonably imagine that when the world has become familiar with the moving platforms of the tense cities of the twenty-first century foreseen by Mr. H. G. Wells, it will also have become familiar with the sight of publicly owned sun-power plants of vast dimensions. This will be the sign that the age of coal and oil has forever passed, to be replaced by hydraulic and direct utilization of sun-power until man has subdued other forces of nature that exist at present only in the minds of those among us who delight in dreams.

DESIGN OF FURNACE

To ensure good combustion it is of the first importance to keep the gases in the furnace as hot as possible, until the oxidation is entirely completed; but this fundamental condition is far from being realized in ordinary practice. In setting a horizontal tubular boiler, for example, it is usual to place one end of it immediately over the furnace, so that it is exposed to the direct action of the fire. In this way the gases, which are at a temperature of perhaps 3500° Fahrenheit as they rise from the fuel-bed, are covered, over the entire area of the furnace, by a metal roof or plate that has a temperature of perhaps 350°. In other words, the entire upper boundary of the furnace is maintained at a temperature some two thousand degrees lower than that of the furnace gases. The absorption of heat by this relatively cold surface chills the gases so that sensible portions of them are cooled below the temperature at which they are capable of uniting with oxygen; and if these cooled portions are not already completely oxidized, they are likely to escape up the chimney unconsumed, and a consequent waste of fuel is the result. The waste that is caused in this way can be minimized by properly proportioning the furnace, but it cannot be really eliminated so long as no attempt is made to burn the fuel under scientific conditions.

HOT WATER

Steam is often used for heating water, the steam being either blown directly into the water, or circulated through a coil of pipe submerged in it. The men often fail to realize that the capacity of water for heat is very great, and that a large amount of steam is required to raise the temperature of even a small tank of water through any considerable range. Hence they frequently draw off excessive quantities of steam in the wash rooms, and thereby waste heat. Wastefulness of the same general nature, though usually of smaller magnitude, may also occur when the water is heated in a special tank and delivered to the wash room through pipes; and when hot water is supplied in this way it is advisable to use a spring faucet, designed to close automatically when the man who is drawing the water releases his hold upon it.

Elimination of Hand Labor an Important Element in Power Plant Operation—Various Methods Employed—Hand Shovelling—Conveyors Essential in a Modern Power Plant

By ROBERT JUNE

Part I

"WHAT do you consider the most important advantage of your mechanical coal handling equipment?" I asked the superintendent of a large manufacturing plant the other day.

His answer, given without a moment's hesitation, was, "Elimination of the large and uncertain labor element. We have twenty 500 h.p. boilers, and at two seasons of the year we require every pound of steam we can get from them, day and night, for weeks at a time. Before we put in our automatic coal handling system we were at the mercy of our coal handlers and passers.

"Time and again the operations of our entire plant were embarrassed, and the work in some departments even brought to a dead stop, by the lack of a full boiler-room crew. We always paid good wages, but the physical conditions under which the men had to work were not good, and on a number of occasions I have been called up at my house late at night, and had to dress and start out in my car on a search for laborers. This was no joke at any time, but when it happened on a cold, rainy night, or with a blizzard for accompaniment, you can imagine the difficulties in getting men to leave their warm beds for any money or other considerations I might offer. On more than one occasion, when I arrived at the plant with my hastily gathered crew, they took one look at the coal piles drowned in rivers of rain and sleet, or else frozen solid, with a forty-mile gale whisking about them, and the thermometer down around zero, and refused point-blank to touch a tool."

"Automatic coal handling has changed all that. Because of its assurance of continuity of operation, the mechanical system we now have is worth several times what it cost us. We would employ it if it cost twice as much per ton delivered to the boilers as hand labor."

That is one point of view. Another man, manager of a good sized plant, said: "We installed mechanical coal handling because we were able to lay out a system which gave us three times as much storage capacity as we formerly had, and we felt it essential to insure an adequate supply of coal at all times."

A third point of view, typical of many, was expressed by a large operator: "We wanted to reduce handling costs as much as possible, and therefore substituted mechanical means for manual handling. Need I tell you that the savings effected have been very large, particularly during the past two years."

As a rule, one good reason is all a man wants as explanation for an action, hence the failure of the gentleman quoted to mention the advantages which appealed to the others. Upon further questioning, however, each mentioned the additional points as supplementary benefits which they enjoyed.

There does not seem to be any doubt that nineteen plant managers out of twenty, who have installed mechanical handling, are thoroughly satisfied that they made a move in the right direction. Some of them, it is true, would make radical changes in their equipment and layout if they had the work to do over again. The point is, that they would do it over. Dissatisfaction, where it exists, is with the application of the system, not with the principle.

As Reginald Trautschold sums up the situation: "The scarcity of coal has made an adequate coal reserve of the utmost importance to every manufacturer, and its high cost necessitates that the fuel be handled at the plant as economically as possible. This condition had tended to make more general the mechanical handling of coal, for no plant, large or small, could now afford to pay the price of manual handling. The attention thus focused on the question of coal handling has resulted in radical changes in the methods employed to store the coal supply and to feed it to the boilers. So effective have been these changes, that it would be little, if any, exaggeration to claim that to-day the boiler plant for a large manufacturing power plant, exclusive of its steam equipment, could be erected and furnished with adequate coal storage facilities, and equipped with a complete system of conveying mechanisms that handle the coal from the point of receipt at the yards to the furnace grates for less money than the most efficient layout of ante-bellum days. This, too, in spite of to-day's high cost of equipment, materials and labor."

Call In An Expert

Having made out such a strong case in favor of the general handling of coal and ashes by mechanical means, a word of caution is here necessary: When you come to consider the proposition as applied to your own plant, get the advice of a consulting engineer, or engineering firm, specializing in power plant design.

I do not mean to belittle the advice and suggestions of your own works construction engineer, or of the engineering departments of the various conveyor manufacturers, or of the engineers and architects who handle your general building construction. These men are all apt to have mighty good ideas, and they should, by all means, be consulted. But, as they are all general practitioners, whereas you need a specialist, the law of averages is decidedly against your getting as good results from their plans as from those of a man who makes power plant design his chief business.

Various Methods Employed

The delivery of coal to the boilers and the removal of ash are usually the largest items of boiler-room expense. The best method of handling coal and ash in any given plant is that which will do the work at the lowest final cost. I use the term "final cost" because insurance of continuity of operation and adequate coal storage are factors which do not appear in a cost-per-ton comparison of methods, but which may have considerable bearing on what may be termed the "earning power" of the power plant.

View of installation at plant of American Thread Co., Shepard transfer crane equipped with grab bucket hoist which is about to enter power house. This plan provided for future extension as will be noted from the photo.

(That is, it may be cheaper in the end to install a particular type of handling system, which will cost more to operate, but will insure avoidance of monetary losses caused by shut-downs, due to lack of coal or to labor difficulties).

That the problem of proper selection of method is not easy is indicated by the almost numberless combinations of means and devices to be found in American plants. The principal factors, which influence the choice of system, are size and location of plant and cost of fuel and labor. The various systems in use may be tabulated as follows:

1. Hand shovelling, without or with wheelbarrow or car.
2. Conveyors.
   - (a) Screw or spiral.
   - (b) Flight or scraper.
   - (c) Apron and buckets.
   - (d) Overlapping dump buckets.
   - (e) Continuous belt.
3. Hoists.
   - (a) Hoist and hand car.
   - (b) Hoist and automatic cable car.
   - (c) Hoist and trolley: telephrage.
4. Cranes.
   - (a) Railroad with clam-shell bucket.
   - (b) Transfer with clam-shell bucket.
5. Vacuum system.
6. Combinations of above. (So-called "silo" system, etc.).

Hand Shovelling

What are the practical limits of economical hand shovelling? No general answer can be given to this question. Its solution depends upon individual circumstances. It is not necessarily a factor of the number of boilers to be served—for instance, the Burroughs Adding Machine Company, Detroit, finds it economical to employ mechanical coal handling for three boilers, whereas the Mulkey Salt Company, of the same city, serves eight large boilers in a thoroughly efficient manner by hand work. The consideration governing the choice of means in each of these cases was point and manner of delivery, and this is the principal factor to consider.

If coal can be dumped from cars or dealers' delivery wagons into bins or on platforms directly in front of the boilers, it is certain that no cheaper means can be devised for hand-fired furnaces. In such instances, one may handle the coal and ashes and attend to the water level of 200 h.p. With hand-shaking and dumping grates, one man may take care of 300 h.p.

In cases where coal cannot be stored in front of the boilers, but must be hauled by wheel-barrow, cart or hand lorry, the practical economic limit of haul is usually 100 feet, and the economic quantity limit, 20 tons per day. While this is generally true, it is not a hard and fast rule. Thus Professor Gebhart states: "Hand-fired furnaces and manual handling of coal and ashes are usually associated with small plants of 500 horse-power and under, but a number of large stations are operated in this way with apparent economy. A notable example is the steam power plant of the Wood Worsted Mill, Lawrence, Massachusetts, in which 40 return tubular boilers are fired by hand. A tipcart, with a capacity of one ton, brings the coal a distance of 100 to 200 feet to the firing floor, and firemen shovel it onto the grate. Four men are stationed at the coal pile. One man drives two carts (one of which is being filled while the other is gone with its load), sixteen firemen attend to the furnaces, and two men dispose of the ashes."

A good man is capable of shovelling 40 to 50 tons of coal in eight hours when unloading a car, provided it is only necessary to shovel the coal overboard. An average figure for handling coal by barrow and shovel is not far from 2.5 to 3 cents per yard up to 5 yards. Above five yards about 2 cents per ton should be added for each additional yard.

Conveyors

Conveyors, like airplanes, are classified as "tractors" or "pushers," depending upon whether they pull or push the load. A third class are genuine "carriers," since the moving parts bear the weight of the load. Of these general classes, the "carriers" are usually more economical of operation and maintenance. Before deciding, however, let us examine the characteristics of the various types.

Screw Conveyors: These are of the "pusher" type, the apparatus consisting of a hollow shaft, attached to which is a continuous spiral of sheet metal. The shaft is revolved by means of a motor in a trough of slightly larger diameter than the spiral, with the result that as the operation proceeds, material placed in the trough is worked forward.

Screw conveyors may be used up to 100 feet, and in sections of limited length up to an angle of 15 degrees. Speeds, capacities, and horse-power requirements are approximately as follows:

SCREW CONVEYORS—HORIZONTAL RUNS
TABLE I.

Diameter Screw in Inches.	Highest R.P.M.	Capacity Tons Fine Coal Per Hour.	H.P. Required for each 10 Ft. of Length (Coal)	Capacity Cu. Ft. Ashes per hour.	H.P. Required for each 10 ft. of length (ashes)
6	115	6	.5	125	.5
7	110	8	.6	175	.5
8	105	14	1.0	350	.5
9	100	17	1.2	425	.6
10	95	22	1.6	575	.8
12	90	35	2.5	950	1.3
14	85	48	3.5	1200	1.8
16	80	80	5.6	2000	2.8
18	75	110	7.7	2700	3.8

*Page 9—C. K. Baldwin, The Robins Conveying Belt Co., quoted by Prof. Gebhart.

Advantages of this type are low first cost, adaptability, and small space required for installation, but these may be offset by high cost of maintenance, due to rapid and excessive wear and tear, by losses caused by breakdowns at important periods, and by the high cost of power to the operator.

Flight or Scraper Conveyors: These are of three types, plain, suspended flight, and roller flight. The trough is of any section, but is usually built with greater width than height. Flights which conform to the shape of the trough are attached to single or double strands of chains. Material is usually discharged through gates in the bottom of the trough.

The design of the plain scraper provides for the suspension of the flights from the chain, which drags them along the trough, pushing the load ahead. Cross bars, having wearing shoes at each end, are provided with the suspended flight conveyor. The arrangement is such that the flights do not

The Shepard transfer cranes equipped with grab bucket hoists over coal storage pile. Coal is received at end of runway shown in background in barges and transferred to storage. Installation Bridgeport Brass Company.

touch the trough at any time. Differing slightly from the suspended type, the roller flight substitutes rollers for wearing shoes.

As between the three types of flight conveyors, service and maintenance considered, there is not a great deal to choose. The general layout of the plant will usually suggest the type to be employed. In this connection, we will illustrate one or two typical installations of flight and scraper conveyors in the continuation of this article next month.

The power required to operate flight

conveyors may be closely approximated by the following empirical equation:*

$$Hp = \frac{AWLS}{1000} \text{ plus } \frac{BLT}{1000}$$

in which

Hp = the horsepower required at the conveyor drive shaft.

AB = constants as in Table II (see next issue).

W = weight of conveyors per ft. of run, lb.

L = distance between centres of head and tail sprockets, ft.

S = speed of conveyor, ft. per min.

T = capacity of conveyor, tons (2,000 lb.) per hour.

X = 1 for conveyors up to 100 ft. centres, and 2 for longer conveyors.

If the conveyor is composed of portions on different inclines, compute the power for each section separately and add 10 per cent. for each change in direction.

As a general proposition, flight conveyors are low priced and offer an economical and efficient means of handling coal and ash in small plants.

Next month we will discuss other types of conveying apparatus.

The Utilization of Peat and its By Products

This Article, One of Several, Discusses the Origin of Peat, Its Properties, the Extent of Canada's Deposits, and Deals With Methods Which Have Been Devised For Its Manufacture, Not Always Successfully

By L. H. BACQUE

THE peat question, or rather the question of finding some practical way to utilize our resources in peat, has lately come very much to the front. The scarcity and the high price of coal have reached such a point, that the people of several of our provinces have suddenly realized that they are utterly dependent on their neighbors in the United States for their supply of coal, unless something can be done to utilize the material available at home.

Any number of public meetings of every description, of Boards of Trade, Municipalities and even Parliaments, have taken place and the general concensus of opinion expressed at these assemblies has been that something must be done, and indeed, it seems almost unbelieveable that such an excellent fuel as the peat we have in Ontario and in several other provinces, should have lain in the earth, neglected and unexploited, as it has done up to the present.

In twenty-seven bogs alone, which have been located and surveyed by the Federal Government in the province of Ontario, there are 63,000,000 tons available of a good merchantable fuel in the shape of a good quality of peat carrying from 25 to 30 per cent. moisture. That such an amount of valuable material should have been allowed to lay there, unexploited, for such a time, appears almost incredible, yet such is the case.

Numerous attempts, it is true, have been made in the past to manufacture this into fuel, but they have all been dismal failures and peat, as a fuel, is now utterly discredited, which may to a certain extent, perhaps, account for the abnormal situation which we find ourselves in.

Why this has been so, however, is the question one is tempted to ask. The question is readily answered. It is because all these attempts have been made in the wrong direction and with a total disregard of the inexorable laws of nature as exemplified in the peculiar characteristics of the peat itself.

With a persistency hard to understand and probably born of ignorance or indifference, or possibly of both, all efforts to utilize the peat as a fuel have been made with the one object in view, viz.: that of transforming it into a hard, compact fuel, easily to be handled and transported, and presenting as a matter of fact all the characteristics which the peat essentially lacks in its natural state.

The main objective of all these attempts has been to compress the peat in it's raw state and so to drive out the large amount of moisture it contains, while at the same time reducing its bulk to such proportions as would make it as nearly as possible similar to the anthracite coal in such common use in Canada, for domestic purposes.

We may as well state at once that it is utterly futile to hope for successful results in this direction. Mr. A. Lencauchez, an engineer of considerable repute as a peat expert in France, effectually disposes of this subject in the Preface to his work on peat, entitled "La Tourbe"—(Peat). He says:

"Regarding this matter (the compression of raw peat) we must observe that all attempts to compress it have failed and that it could not very well be otherwise, for nothing can take the place of nature and of the molecular contraction provided by a slow condensation lasting ten to fifteen days. The stroke of a press can only dislocate the moist substance of the peat without expelling all the water it contains. Wood which carries 50 per cent. moisture when green, only carries 20 per cent. when dry; but, we ask, could the stroke of a powerful press ever drive out instantly 30 per cent. of this water (if ever it did drive it out), without absolutely reducing to powder, the fibre of the wood? That is the reason why the aimless compression of raw peat must be considered as Utopian."

The event in Canada, as well as in other countries, has proved the truth of this statement.

And not only has it proved impossible up to the present to dry raw peat by compression, but difficulties almost as great have been encountered in all attempts to dry it by artificial means. This is not to be wondered at when one considers some of the peculiar character-

Illustrations Courtesy Department of Mines, Ottawa

PEAT READY FOR THE MARKET. ALFRED, ONTARIO

istics of peat, which are: (1) That when in the raw state it carries from 85 per cent. to 95 per cent. moisture; (2) that it parts with only a small part of this by natural drying, always retaining at least 15 or 20 per cent. water, and (3) that when dried absolutely by artificial means, it immediately reabsorbs it's quota of moisture from the atmosphere as soon as it is again exposed to its action.

Moreover, the excessive amount of utterly useless water to be handled when harvesting the peat is also a serious handicap to be overcome by the manufacturer. If we take 100 pounds of air-dried peat, for instance, carrying 15 per cent. moisture, we find that this material contains 85 lbs. of peat substance and 15 lbs. of water. On the other hand, 100 lbs. of raw peat contain 90 lbs. of water and 10 lbs. only of peat substance. so that to produce 85 lbs. of peat substance, contained in the 100 lbs. of dry peat, we will have to extract, handle and treat industrially, 850 lbs. of the raw material and get rid of:

$$\frac{850 \times 90}{100} - 15 \text{ or } 750 \text{ lb.}$$

of water.

To get one ton of absolutely dry peat, by whatsoever process we dry it, artificial or natural, we must handle 10 tons of the raw material and evaporate or dispose of in some way close on nine tons of water.

The problem, it must be admitted, is not one that promises to be easily solved, nor does the prospect improve when one considers that artificially dried peat is no sooner exposed to the air than it promptly takes up again its percentage of moisture and crumbles away into dust as an immediate result of this re-absorption of water.

Summing up these points, it may be stated in a general way that the manufacturer will always be confronted at the outset with three marked and absolutely characteristic difficulties, viz.:

1. That of harvesting, handling and manufacturing a mass of raw peat containing approximately 90 per cent. water and weighing ten times as much as the finished product to be eventually turned out and marketed.

2. That of evaporating or otherwise getting rid of nine-tenths of this superfluous weight of water by natural or artificial means.

3. And when the peat is as dry as nature will allow it to become, then to further dry and compress it, or make it into coke or briquettes, so as to fit it for any special purposes it may be intended for.

As a corollary of the above, it stands to reason that the most economical way of utilizing peat is that one which will allow the consumer to get the greatest possible heat efficiency out of it, though allowing it at the same time to retain the greatest possible proportion of moisture, and so enabling the manufacturer to produce it at the smallest possible first cost for evaporating this water.

PEAT BOG IN THE COURSE OF EXCAVATION WITH THE AUREY'S EXCAVATOR AT ALFRED, ONT.

Now, before going any further, it may be stated at once that the object of this paper is to show that the most economical, as well as the most practical and elegant solution of this problem from a scientific point of view, will be found to be the gasification of the peat, carrying from 25 to 30 per cent. moisture, by treating it in gas producers, with or without recovery of by-products, and utilizing the gas for power purposes in gas engines, or for industrial and domestic heating purposes.

This much being said, it will be in order to see just what peat is; what its peculiarities are and what are the best and most economical ways in general use abroad to manufacture it into a useful fuel.

Origin of Peat

The geological origin of peat not being relevant to the main subject of this paper, it will be sufficient to state that peat, as it usually occurs in nature, is not properly speaking a mineral, nor is it exactly a vegetable, though it has a vegetable origin. It is a substance which is the product of the destructive fermentation and gradual decay of numerous varieties of aquatic and semi-aquatic plants. Successive crops of the plants grow to maturity, then die and gradually rot away to form deposits at the bottom of lakes or ponds in which the plants grow. In the course of years, these successive deposits accumulate and gradually fill up these ponds, to such an extent that sometimes the ponds are completely filled up and acquire the consistency of solid earth, forming lands upon which trees and other kinds of vegetation begin to appear. Generally, however, the deposits simply take the shape of marshes or "bogs" in which there is more or less water present. At times, there is so much of this water that the peat has to be harvested by means of dredges, similar to those in common use for dredging sand out of rivers and lakes.

Color

In color peat ranges from light yellowish or straw tints, through various shades of yellowish or reddish brown, to a dark brown and even to black, these colors being all darker when the peat is wet. The lighter colors, however, usually change to a dark brown or black color after the peat has been macerated and exposed to the air.

In good peat beds, which have been exposed to the action of the air during the course of their formation and where the peat matter has therefore been thoroughly well aerated, there is a progressive darkening of the peat substance from the upper strata down to those at the bottom of the deposit.

The quality of the peat being indicated to a certain extent by its color, the object of the manufacturer when harvesting it, will be to endeavor to take up an equal proportion of all the strata in the bog at every stroke, to thoroughly macerate the mixture and so to obtain a thoroughly uniform and homogeneous mass, representing as nearly as possible the best average peat obtainable from the cross section of the bed.

Texture

The structure of peat varies considerably according to its origin and varies also in the different strata of one and the same bog.

The top layers of most bogs, for instance, contain a quantity of fibrous matter and partly decomposed grasses and plants and when dry present approximately the appearance of slightly compressed, dried tobacco. On the other hand, the bottom layers of filled bogs are made up of a soft oozy substance of a dark brown or almost black color which, when thoroughly macerated and mixed with the other layers, forms a soft, greasy, plastic substance of considerable density and presenting all the characteristics of potter's clay.

The finer the grain of this substance, and the darker its color, the better the fuel will be as a rule when it is dry.

There are certain kinds of thoroughly well humified fine-grained peat which,

THE DRYING OF PEAT IN OPEN FIELDS BY THE SUN AND WIND. ALSO METHOD OF TRANSPORTING

when well machined, will dry into a dark, almost black, close-grained substance, as hard as wood and which can be carved like ebony.

The nearer this condition a dried machine peat can attain, the better fuel it will make.

In the north-eastern parts of France, where our boys have been fighting a great battle, and in the near neighborhood, this material is made into a very much prized quality of coke which is used for metallurgical purposes. It is much valued for this use on account of the total absence of sulphur from its composition.

In a general way it may be stated that the texture and greater or lesser uniformity of a given peat will depend upon

1. The mode of formation of the bog, whether filled or built up;

2. The general type of plants which have contributed to its formation, and

3. The greater or lesser degree of their disintegration, which is indicated by the color of the material. The more thoroughly disintegrated the material, the better humified it is; the darker its color and the finer its grain, the better the fuel will be.

Water Holding Capacity of Peat

One of the most characteristic features of peat is its great capacity for holding water in various ways. When in its raw state in the bog, for instance, it holds from 85 to 90 and even 95 per cent. water, which it is not easily separated from.

Mechanical treatment will not get rid of any of this water to any extent, the result of very high pressures being to crush the peat substance and destroy it's usefulness as a fuel.

As a rule, this treatment will not reduce the moisture content to less than 70 per cent. and after that point, the peat, if required with a smaller moisture content, must be further dried by either natural or artificial means.

What is known as air-dried peat may be dried by natural means down to 18 to 20 per cent. moisture according to climate, but cannot be dried any more after this point is reached, unless artificial heat is applied to it. This, however, makes the fuel so costly that it should only be resorted to when the fuel is required in the absolutely dry state for a specific purpose, and in that case it should always be used at once before it has a chance to absorb any moisture again, which it will do immediately upon being exposed again to the atmosphere after drying.

Peat is only reduced to an absolutely dry state either when it is required as a fuel to produce high temperatures, and in such cases is used as soon as made, or else when it is intended to be coked or briquetted. In the latter case it must be impregnated with some waterproof binder, if it is to be kept for any length of time before being used.

Composition and Fuel Value of Peat

The formation of peat bogs and the physical processes of this formation take place under such a variety of conditions that it is difficult to give what may be termed even an average standard composition of peat. However, a prominent authority gives the following, around which average compositions will vary, for an air-dried, machine made peat, viz.:

Fixed carbon, 27 per cent.; ash, 13 per cent.; raw tars, 5 per cent.; nitrogenous liquids, 34 per cent.; permanent gases, 20 per cent.; various, 1 per cent.; total 100 per cent.

Another authority gives the following values for an average peat obtained by distillation in closed retorts, of the peat previously desiccated at 200 deg. centigrade, viz.:

Fixed carbon, 30 per cent.; gases by distillation, 36 per cent.; tars, 7.5 per cent.; acid liquids, 14.5 per cent.; ash and sundries, 10.5 per cent.; free nitrogen, 1.5 per cent.; total 100 per cent.

The fixed carbon, tars and gases being the only constituents which will burn, give the peat its heat value and in this connection the composition of the permanent gases themselves will be of interest.

These gases are approximately in the following proportions:

C_2H_4., 2.5 per cent.; C.H., 7 per cent.; H. C. Vapors, 1.5 per cent.; H., 40 per cent.; C. O., 30 per cent.; CO_2, 14 per cent.; Nitrogen, O. and sundries, 5 per cent.; total, 100 per cent.

Or 81 per cent. by volume of combustible gases, and 19 per cent. without any fuel value.

In other words, an average peat desiccated at 200 deg. centigrade, would contain approximately 65 or 66 per cent. of combustible material.

Mr. Lencauchez, of Paris, France, an eminent engineer, of great experience in the use of peats for industrial purposes in the Somme and in Picardy, gives the following as the limits between which peats will vary in that country, viz.:

Fixed carbon, 20 to 34 per cent.; products volatilized by distillation in retorts, 35 to 50 per cent.; ash, 20 to 4 per cent.; hygrometric water, 25 to 12 per cent.; total 100 per cent. each.

The following analysis of Canadian and American peats will show that their composition is very much the same and therefore, that whatever applies to the latter, applies fairly well to the former.

One difference in favor of some of the Canadian peats is that they carry very large percentages of nitrogen, which, as we will see later, is a valuable feature.

American peats. (Analysis U. S. Geol. Survey) Moisture free. Desiccated at 200 deg. C.

Volatile matter	57.98	60.28	56.38
Fixed carbon..	27.75	29.89	36.31
Ash	14.27	9.83	7,31
Sulphur	0.71	0.73	1.07

Canadian peats. (Analysis of the Mines Branch of the Department of Mines, 1913-1914) Moisture free. Desiccated at 105 deg. C.

Fixed carbon	25.	19.	29.	27.	22.	23
Volatile mat.	68.	61.	62.	61.	67.	61
Ash	7.	21.	9.	12.	12.	16
Cal. val.	9100	7500	8900	8100	7900	7900

Referring more particularly to the above, the department gives these peats as carrying percentages of nitrogen varying from 1.5 per cent. to 2.6 per cent., the latter figure being particularly high and giving the peat a striking value not as a fuel, but as a raw material for the manufacture of nitrogenous fertilizers.

Heating Value of Peat

The calorific power of peat will vary, like its composition, within rather wide limits. The ash and the water content are the two factors which will affect it most.

In a general way, it may be said, according to the department data, that this heating power will vary from 6200 to 6500 B. T. Us. for air-dried, machine peat carrying 25 per cent. to 30 per cent. moisture, to 7200 to 7400 B. T. Us. for dry briquetted peat.

Incidentally let us note that these figures show that drying and briquetting peat does not increase its heating value more than 15 per cent. or thereabouts, a fact which must give food for thought to those who advocate the indiscriminate briquetting of peat as a condition "sine qua non" of its success as a fuel.

Specific Gravity of Peat

The specific gravity of peat, like its composition and its heating power, varies considerably according to conditions and runs from .450 to .460 for air-dried, macerated peat to .750 and even 1.0 or 1.05 for artificially dried, compressed briquettes. These figures, however, must not be taken as absolute for, according to the drying and the treatment given to the peat its weight like its composition and heating power, can vary within very wide limits.

General Remarks

In a general way, it may be added that the low specific gravity of this fuel, coupled with its low heating power, have constituted a serious handicap against its adoption as a fuel in this country.

It will take from 1½ to 2 and 3 times the weight, and therefore from 4 to 8 and even 10 times the bulk of ordinary machine cut peats to furnish the same amount of heat as a given weight of coal.

These peculiarities, inseparable as they are from the very nature and physical characteristics of the peat, as well as the misdirected efforts to utilize this fuel by futile attempts to do away with them, have been the cause of all the failures recorded up to the present and the consequent lack of popularity of the fuel.

The proper way of utilizing our peats has never been attempted and seems to have been absolutely ignored from the beginning in this country, and it is the purpose of this paper to show that peat can be advantageously utilized and that in more ways then one, even when in competition with the cheap coals to be obtained in this Province.

PANORAMIC VIEW, ALFRED PEAT BOG

HOT BEARINGS

By M. M.

A wise manufacturer always takes precautions to avoid the bearings in machinery being heated and takes frequent steps to satisfy himself that the men in charge of this matter are really attending to their duties. If this is neglected very serious damage is involved. Some bearings are normally hotter than others and in some cases a bearing may feel uncomfortably hot to the hand and yet may be quite satisfactory, though this is seldom the case in any clay-working plant where the machinery is heavy and runs comparatively slowly.

Among the numerous causes of hot bearings the following are the most important:—

(a) Lack of lubrication, due either to an insufficient supply of oil or grease by the man in charge or to some defect whereby the lubricant cannot reach the part of the bearing where it is required. This defect can be remedied without much trouble.

(b) An unsuitable lubricant, such as using a grease where an oil is required, or a thin oil instead of a thick one. In some cases even a slight increase in the thickness of the oil may make all the difference to the running of the bearings and no pains should be spared to ensure a suitable lubricant being used. It often happens that a cheaper oil or grease may be substituted for the one being used, but the aim should never be to use a lubricant which is sold at a low price, but one which proves to be cheap in use because so little of it is required to keep the bearings in good condition. In many cases the substitution of grease under slight pressure (as in a Stauffer lubricator) will prove more efficient and much cheaper than the use of thick oil. The choice of a lubricant should be based on trials and on actual experience and not on the recommendation of men with little or no knowledge of the conditions.

(d) Dirt in the bearings introduced with the lubricant or in the form of dust. This sets up friction and soon caauses an evolution of heat. The remedy consists in cleaning the bearing thoroughly, using a lubricant free from gritty matter and protecting the lubricating hole in such a manner that no dust can enter the bearing. A light cover will often save a large amount of trouble in this respect, particularly in dusty places.

(e) The clearance in the bearing may be either too large or too small. If the former lubricant will not be kept properly to its work and if the latter there will be an insufficient supply of lubricant owing to the small space through which it has to pass. The remedy in either case is to place the parts of the bearings in such relationship to each other that the correct amount of clearance is obtained.

(f) Lack of alignment will often cause overheating of the bearings, as the machines will not be truly parallel to the driving shaft and the pressure exerted by the belt or gearing will be greater at one part than at another.

(g) Badly made or badly lined bearings usually "work hot" and no amount of lubrication will prevent this. Unless care is taken in relining a bearing the white metal may be left too rough and thus prevent the proper flow of the lubricant or even the total lack of lubrication at certain points because the lining is in contact with the moving part.

When a bearing is overheated the first thing to do is to apply more lubricant and to observe carefully whether this has the desired effect. If not, a thinner lubricant may be applied if the nature of the bearing permits, though the use of thin oil is seldom a permanent remedy for hot bearings. If this does no good, the bearings should be slackened slightly as the clearance may be insufficient to permit the lubricant to flow properly. In some cases it may be necessary to slow down the engine until the bearing cools and at the same time to examine it as far as conditions permit. It is best not to stop the engine or machine entirely as the bearing may then adhere to the journal and it will be impossible to restart it without damage. On no account should a bearing be cooled by pouring water on it. This usually causes such severe contraction that the shell is weakened and may be cracked. If other means of preventing the bearing from being overheated fail, it will be necessary to take it to pieces, examine it carefully and see whether the cause of heating is included in the ones mentioned above. If it is none of these, the case is so abnormal that a specialist will be required to diagnose the cause and provide a remedy.

Talbot Boilers and Engines Made in Canada

Improved Design Results in Saving in Space and Increased Efficiency Over Standard Types of Boilers and Engines—A Description of the Contra-flow Boiler and New Uni-flow Engine

THE developments and improvements that have taken place during the last generation in the manufacture of boilers have been confined very largely to construction details and arrangement of parts, but the principles involved in carrying large volumes of water, with circulation by gravity, has remained the same in all of them, and to some extent the advancement in steam generation has not kept up with the general march of industrial progress; therefore the contra-flow type of steam boiler, with the water spread over a thin film over the surface, represents the last word in the known science of boiler construction. A boiler of this kind occupies about one-seventh the space per H.P. of that required for a Scotch boiler of the same capacity, thus permitting of additional cargo space, or small vessels for stated tonnage. In these oil-fired types of boilers no brickwork is necessary, and with the saving of space it is claimed that they can be operated cheaper than any known power-producer. Automatic control minimizes the labor factor, as one attendant can easily take care of a large group or battery of boilers.

The Talbot contra-flow boilers here described were invented by Paul A. Talbot, president of the Talbot Engineering Corporation, of New York. The Uni-flow engines here illustrated are also of his design.

General Description

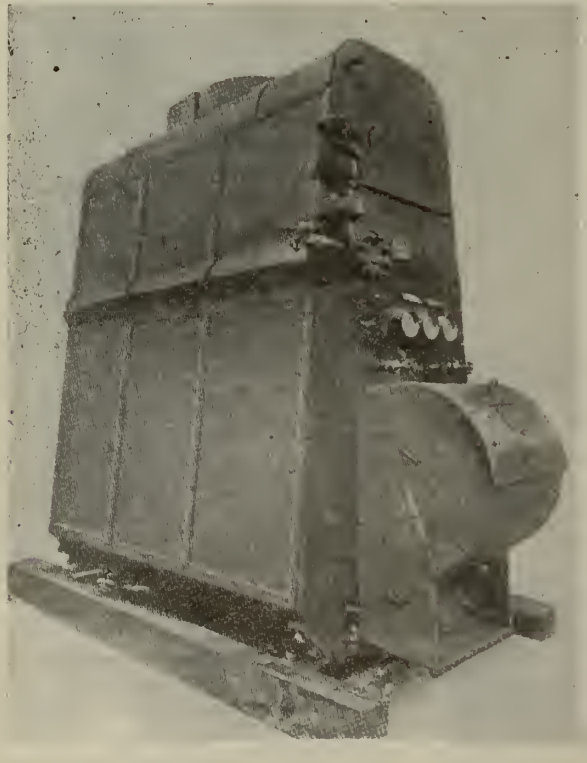
This is essentially a boiler of the contra-flow type, water entering near the stack and leaving in the form of steam near the furnace. The circulation is through water tubes and is forced at a high velocity by means of a pump, doing away with a water drum. By preventing gravity circulation, the steam is drawn directly from the lower tubes, eliminating the steam drum. The boiler is internally fired, and hence self-contained. Feed water and fuel burners are automatically controlled to adjust the boiler to widely varying demands for steam. The boiler should not be confused with "flash" boilers in which the heat-charged tubes furnish steam in direct proportion to the feed supply without regard to the control of the fire. By means of the high velocity, forced circulation and contra-flow principles, the evaporative capacity of the boiler is largely increased.

Any or all of the tubes may be readily removed and replaced without disturbing any manifolds, pipes or connections. Official tests recently carried out in the Navy Yard, New York, included a tube-renewal test of a 100 h.p. boiler. A tube was removed from the boiler under 250 lb. steam pressure and replaced by another tube in 61 seconds, the total period between the time of shutting off the fire and feed water and the time of regaining full pressure and maximum capacity of operation being 3 min. 16 sec.

An idea of the general construction of the boiler may be obtained from Figs. 1 and 2. Fig. 1 shows the front and Fig. 2 the rear of the boiler with the casing removed. Fig. 3 shows complete boiler with its casing. The illustrations are of a boiler having an evaporation of 15,000 lb. of water per hour with ¼ in. of water draft, 20,000 lb. per hour with 1 in. draft and double the normal capacity at slightly above 2 in. draft.

The frame consists of front and rear sections, roughly resembling horseshoes in shape, fastened together at top and sides by lateral ties, and at the bottom by the ash pan and additional ties. The stack ring and upper panel work are supported by framework bent to conform to the curve of front and rear frames. For fastening the boiler in position, feet are provided which are bolted to the main frame through the ash pan. The door frame, of angle cross-section, is fastened at the top and bottom to the main frame and serves as a support for regulating valves shown in Figs. 1 and 3 and described more fully later.

The tubes throughout the boiler are



FRONT OF BOILER WITH CASING

REAR OF BOILER, CASING REMOVED

all alike. As will be seen in Fig. 4, the crucible steel header consists of two sets of overlapping compartments, into one of which is screwed the open-end field tubes, and into the other the generating tubes, there being an annular space between the two tubes. The end of each generating tube is welded together so as to close it. These closed ends are free to expand and are supported in front by perforated sheets of metal. The method

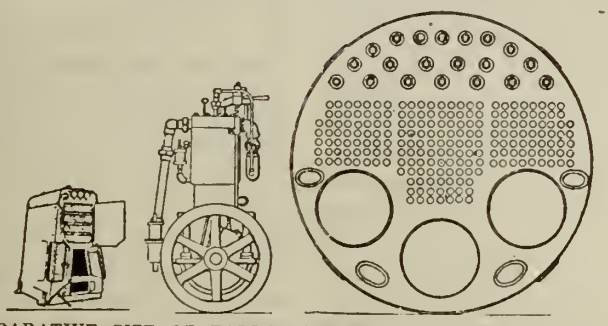


FIG. 3—COMPARATIVE SIZE OF TALBOT BOILER, GAS UNIT AND SCOTCH MARINE BOILER OF EQUAL CAPACITY.

of fastening the tubes into the headers is shown in Fig. 5. Both tubes are threaded with double the standard taper, which makes it easy to remove them. The fit is sufficiently tight to hold a pressure of 1,000 lb. per sq. in., using standard weight pipe.

Five sets of tubes with horizontal headers are placed above the combustion space, and on each side of the combustion space is placed another set of tubes with headers arranged vertically. The rear of the furnace is closed by a wall containing water-circulating passages connecting the tubes on the sides, as shown in Fig. 2.

Between each set of headers is a trap connection, shown in Fig. 2. These traps perform the important function of preventing water from draining by gravity from one header to the next below, until sufficient water is forced into the upper header. The formation of steam prevents the water from siphoning when circulation is at rest and the correct amount of water is thus maintained in each header in readiness for full capacity demands.

Accessibility. There are three doors in the front of the boiler, which, when opened, give access to the free ends of all the tubes. Any tube can be removed by applying a wrench to its end and unscrewing it from its header.

Operation

The circulation of water is maintained by a pump, delivering the feed water to the main check valve at the bottom of the door frame, from whence the water rises in a pipe and passes around the door frame to the regulator valve. The water then passes to the rear of the boiler to the uppermost set of tubes. In order to understand the circulation through the tubes, reference must be made to Fig. 4, which shows a typical header and tubes forming a single section, the path of water through it being indicated by arrows.

Having passed through the first set of field tubes and returned to the inner compartment of the header by way of the annular space in the generating tube, the water returns to the front of the boiler through a similar annular space in next set of tubes and back to outer compartment of the header by way of the inner field tubes. This process is repeated until the water has traversed to the opposite end of the header, where it passes out through a trap connection to the header immediately below. Passing from header to header, the water has a general downward direction to the set of tubes, which is on the left side of the furnace, as seen in Fig. 2. The circulation through all sections of tubes is the same.

Referring to Fig. 2 the steam or water from the set of tubes on the left to the furnace enters a rear wall which is partitioned in order to carry the water at high velocity from one side to the other until it is finally discharged, at the bottom of the right-hand corner, into the set of tubes on the right side of the combustion chamber.

During this passage the water has gradually changed to steam, and it now leaves the last set of tubes through the herringbone steam separator at the back of the boiler and enters the steam pipe, crossing at the front of the boiler where safety valve and steam nozzle are located. The separator drain passes to the front of the boiler where the valve controlling it is located.

The length of water passaged from the point of entering the boiler to the point of leaving it varies with the size of the boiler. The passage in a 1,000 h.p. boiler is 795 feet long, 668 ft. of which is through tubes. The areas through which the water flows also vary with the boiler and are restricted to increase the velocity of flow.

The friction of water and steam by reason of the restricted areas is about 100 lb. at normal load. This friction increases as the load increases.

The velocity through the boilers in which large tubes are used is much greater than when smaller tubes are used. Thus the velocity of the steam in the last stages of the boiler varies from 6,000 to 12,000 ft. per min. depending upon the size of the boiler tubes used. This velocity increases, of course, as steam is formed, so that the velocity in a large boiler is about 500 ft. per min. in the first and 12,000 ft. per min. in the last passages when in the form of steam.

A high rate of evaporation is obtained because of the high velocity of water through the tubes. The tubes which line the furnace evaporate as much as 30 lb. of water per sq. ft. of heating surface, while the average, including economizer and superheating surface, is 8 lb. per sq. ft. rated capacity.

The formation of scale is prevented by the high velocity and consequent scouring action of the water, which keeps the solids in constant motion. The actual velocity great enough to prevent scale is not known, but it has been determined that with a velocity as low as 60 ft. per min. and very poor water, mud forms in the economizer section of the boiler. The water tested was alkali of 27 degrees hardness, such as is found in desert regions. With a normal velocity of 500 ft. per min., such as is used, a minimum velocity of 150 ft. per min. can be maintained at partial loads. It has been found that at very low velocities the deposits have been confined to the water portion of the boiler, where the temperatures are between 100 and 150 deg. Fahr. As the entire heating surface is active and subjected to these high velocities, feed water purifiers are not necessary for this boiler.

The Soot Blower

The soot which forms on the economizer surface of the upper sets of tubes is blown from them by longitudinally directed steam jets situated near the ends of the tubes. Steam is supplied from the main steam pipe, and valves for the control of the jets are on the front of the boiler. The jets have proved a satisfactory method of keeping the surface relatively free from soot. The tubes at the side of the furnace are practically free from soot, and it is probable that if any soot collects on them it eventually ignites. Exterior as

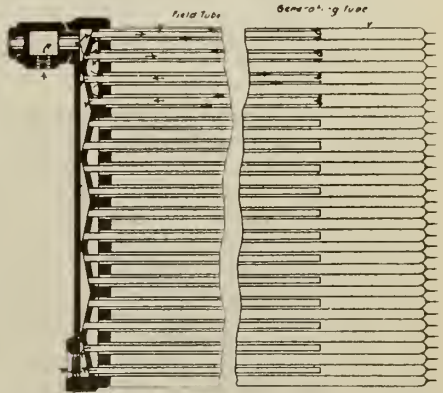

FIG. 4—DIAGRAMMATIC SECTION THROUGH HEADER AND TUBES. ARROWS SHOW COURSE OF WATER CIRCULATION.

well as interior surfaces of the boiler, therefore, are always clean, eliminating the periodic overhauling and cleaning.

Thermostatic Control

The expansion of one of the tubes of the last set at the side of the furnace under the varying temperatures of steam contained within it is multiplied by means of levers, and is utilized as an automatic thermostatic control of both water and fuel supply. Arrangement is made so that the operator may easily and quickly adjust the thermostat to meet the demands. The slightest rise in

temperature of the outgoing steam causes sufficient expansion of the tube to open the regulating valve on the front of the boiler and admit a greater quantity of water, thus lowering the temperature of the steam. In case the operation of the thermostat has not prevented the rise in temperature, as might happen under partial load or insufficient water supply, it will cut off the supply of fuel to the furnace. At low temperatures, the supply of fuel is increased by this same thermostat.

Details of the thermostat. The expansion and contraction of the tube and the movement of the regulating valve are shown by a gauge, which is arbitrarily graduated for convenience in indicating the relative temperatures, and may be calibrated by means of a mercurial thermometer so that the operator may judge from it the temperature of the steam. Thus it might be determined that with the gauge reading 2 3-8, the temperature of the steam is 650 deg. Fahr. Having determined the point for the temperature he desires, the operator can regulate the thermostat to maintain the gauge at this point. This reading is checked occasionally, as changes in the frame, header or tube, due to wear or seasoning, may make corresponding changes in the calibration of the gauge, so that some other point registers the 650 deg. which the operator is trying to maintain. This temperature gauge serves the purpose of the water column of the ordinary boil. The temperature of steam delivered tells operator whether or not the supply of water is adequate, as it is obvious that with too little water, at full capacity, the temperature of the steam will rise and indicate this condition on the gauge. Alarms may be attached, if desired, but are unnecessary, as the fire automatically is shut off before the boiler is damaged. When steam temperature drops, the normal supply of water is attained.

Hand Valve

The action of the automatic valve is fairly close, but due to the fact that the regulator tube is not instantly affected there occur periodic changes in the temperature and pressure. A hand valve is provided for eliminating this action under normal loads. This valve is arranged to shut off completely the supply of water when closed, and is marked with arbitrary graduations from which the operator may determine at what point it should be set for the best results. When the hand valve is closed too much, it is obvious that the supply of water may be so limited that the temperature will rise to a point where the fuel valve will close. When the valve is opened too much, there will be a periodic variation in the temperature of the steam, due to the lag of the controlling thermostat. The point should be determined, therefore, which will allow the regulating valve to be opened all the time, preventing the periodic variation in temperature due to too frequent shutting down of the fuel valve. The accuracy of adjusting this valve determines the accuracy of temperature control under full-load conditions. Experience has shown that on a 25 per cent. load the valve does not require adjustment, but the temperature of the steam will be much less, due to an oversupply of water to a reduced fire. By readjustment of the valve the full-load temperature can be maintained at fractional loads. At less than 25 per cent. capacity a readjustment is necessary to prevent the periodic variation in temperature. The ordinary fireman can easily maintain a constant pressure and temperature by means of this hand valve.

Oil Burner

A steam automizer oil burner is arranged at the front of the boiler near the top of the inflow of air for combustion. The air is heated and carried in a general downward direction by the air duct, a short-metal addition to the front of the boiler having an S-shaped channel. The quantity of the air can be adjusted by air dampers in this duct. Highly superheated steam is used to heat and vaporize the oil and to promote the velocity of the hydrocarbon mixture, which issues from the burner tips. Very heavy Mexican oil, 11 Baume, can be used in this burner. A number of burner tips shoot the flame downward into a firebrick target at the lower rear end of the furnace. This refractory target or oven is designed to distribute the heat uniformly over the entire heating surface. Temperatures of 3,800 deg. Fahr. are obtained within this oven, but as few bricks are used, the upkeep is small.

The intensity of the fire is easily controlled by increasing or decreasing the volume of steam used in automizing the oil. The flame has the effect of a large blow torch, and as the velocity is carried to an extreme, considerable noise is experienced. This is not a detracting feature in marine practice, as it is confined to the fire room.

Furnace Jacket

As heating surface surrounds the furnace on all sides, the insulation of the jacket is easily accomplished. The insulating material is applied in plastic form and fills the entire space between the sheet-metal casing and tubes themselves.

While this system is preferred, the various methods of applying insulating material in boilers having sheet-metal jackets may be used, or brick settings may be installed where space, weight and vibration are not settings for consideration.

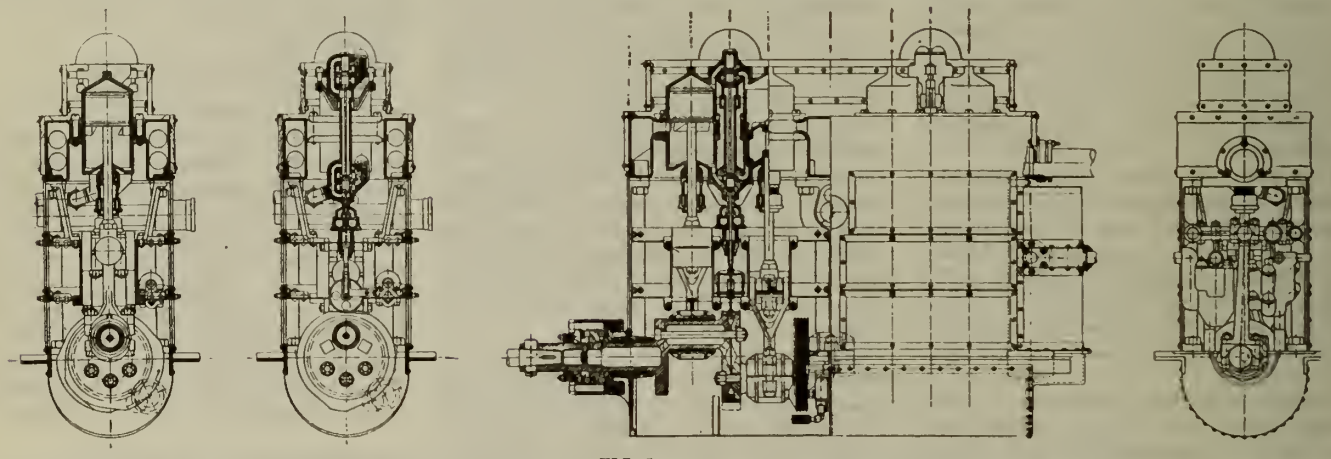

FIG. 5
TALBOT 4-CYLINDER UNIFLOW MARINE ENGINE. WORKING PRESSURE 500 LBS. PER SQ. IN. 1,500 I.H.P. SIZE HAS CYLINDERS 20 IN. x 20 IN. FOR 160 REVS. PER MIN. WEIGHT, 20 TONS. TWO PISTON VALVES SERVE ALL CYLINDERS. STEAM CONSUMPTION 10 LBS. PER H.P. HOUR.

Effect of Forcing

The thermal efficiency of this type of boiler is affected in much the same manner as in boilers of other types, although the drop in the efficiency curve is not so pronounced at higher draft pressures and higher evaporative rates, due to the fact that when forced the economizer surface in the upper part of the boiler is correspondingly increased and the stack temperatures are relatively lower. More water is introduced, and the superheating surface is reduced nearly in proportion as the load is increased.

The Talbot steam power plant is usually installed with the boiler at the side of the engine. In fact, the boiler and engine are one unit, and the plant has the advantage with other oil engine installations of occupying a minimum of space and affording a maximum of steaming radius to vessels equipped with it. The engine proper has four cylinders, which are all of equal diameter and stroke, and it is built particularly for the use of superheated steam. The piston rods and valve stems run in an oil bath

Transformer Connections for Power Transmission

Part Two of an Article Descriptive of Various Types of Transformer Connections in Common Use and the Characteristics of the Resulting Circuits

By GORDON KRIBS

2. Star-Star, or Y to Y Connections

IN the Star or Y arrangement each transformer has one terminal connected to a common junction or neutral point—the three remaining terminals being connected to the three-phase lines as shown in diagram Fig. 19.

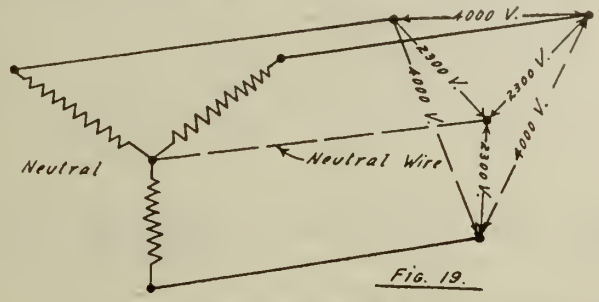

FIG. 19 STAR CONNECTED TRANSFORMERS

In a system using Star-connected transformers, there may be either 3 or 4 transmission or line wires. In case there are three they are all phase or power wires; if four, one of them is a neutral wire, and is connected to the common junction of the transformers. It is often of steel, since it does not carry anything more than a balancing current which in a balanced system is usually small and often of triple the system frequency. In high tension transmission systems the neutral point of a Star connected system is usually grounded, either direct or through a resistance which has a steadying effect on the delivery voltage of the transformers owing to the fact that the electrical neutral point has a tendency to wander from the physical neutral unless tied down by means of a definite ground wire or by reason of the fact that the secondary is delta connected.

In the appended diagram, Fig. 20, the neutral wire is shown dotted, and may or may not be used.

It will be seen that each transformer, both primary and secondary, has one terminal connected to a common point or neutral while the other terminal is connected to the line. This method of connection is not as good for high voltage lines as the Delta-Delta connection or the Delta-Star or Star-Delta to be given later, for the reason that electrical waves of 3, 5, 7 or 9, etc., times the true frequency are liable to be formed—due to magnetizing currents in the transformers and these harmonies, as they are called, are liable to generate destructive high frequency voltages in the circuit. For low voltage lines—this connection is satisfactory. In order to draw a voltage diagram of a Y connected bank of transformers we may proceed as follows:

Let us name the common point in Fig. 20 "X" and each of the other terminals respectively a, b, c.

Now referring to Fig. 21.

Draw A′ X′ vertically representing 2,200 volts—the voltage across the transformer a—x, and draw b X′, and c X′, both equal in length to a X′, but 120 deg. apart so that at X′ we have three angles of 120 deg. each. Each of these lines represent 2,300 volts, being the neutral or common point and the distances a b,—b c,—c a, as measured on the diagram represent the voltage across the lines, which in this case is 4,000 volts.

Since a line is taken off from the free terminal of each transformer it is evident that the current in each line is the same as that in each transformer. The voltage across lines however is seen from the diagram to be 1.73 times the voltage across each transformer, i.e., the voltage across each transformer is only $\frac{1}{1.73}$ or 58 per cent, of the line voltage.

In other words the same ratios which held good for currents in the Delta connection—hold good for voltages in the Y connection.

Unlike the Delta system of connections if a transformer in a Y connected bank of transformers burns out, it is impossible to supply three phase service as may be seen from the diagram Fig. 22.

It will also be seen from the diagram that the phase angle between the transformer voltages is 30 deg. Since at unity power factor the voltage and current in the transformer are in phase, it follows that with a Y connected system, as in a Delta system, there is a phase angle between line voltage and line current of 30 deg.

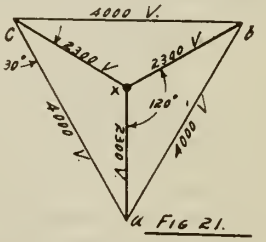

FIG. 21—VOLTAGE RELATIONS STAR CONNECTION

(3) Delta-Star Connection

The Delta-Star connection is simply a combination of the two previous methods in which the primary is connected Delta and the secondary, Star, as in the diagram Fig. 23.

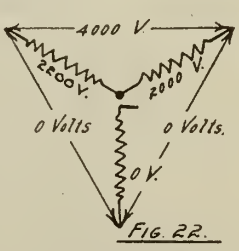

FIG. 22

This system is largely used in stepping down from a medium transmission voltage such as 44,000 volts, 26,400 volts or 13,200 volts to 4000 volts. This latter voltage has lately come into considerable use since standard lighting transformers may be used and yet considerable money can be saved due to the use of the higher voltage in distributing systems and short transmission lines of small capacity. It has the same disadvantage as the straight Star connection in that if one transformer is burned out,

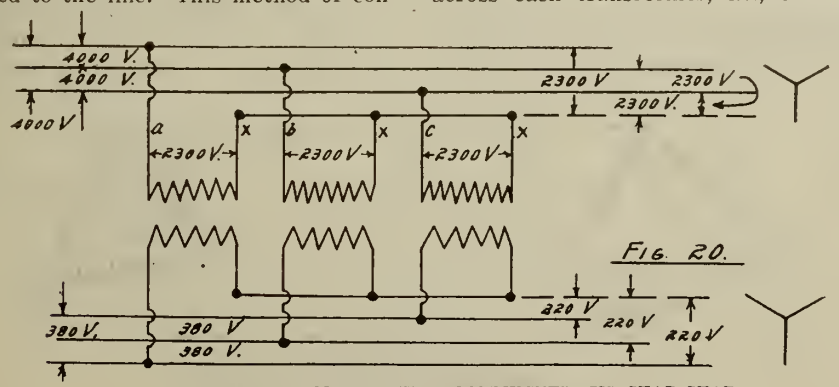

FIG. 20—TRANSFORMERS CONNECTED UP STAR-STAR

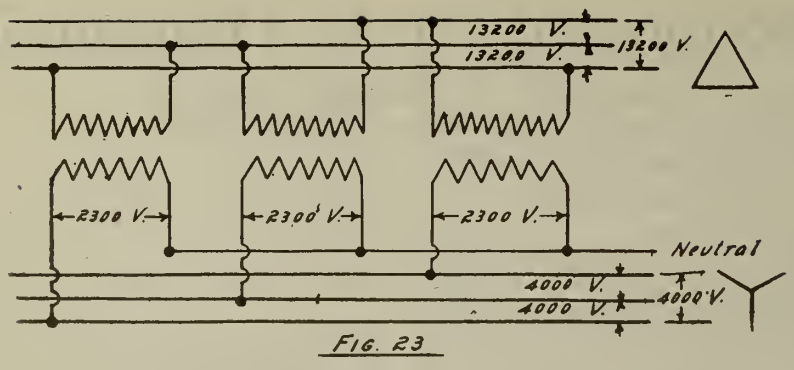

FIG. 23—DELTA STAR CONNECTION

three phase service cannot be given.

(4) Star-Delta Connection

This system of connecting up a bank of transformers is usually used where it is desired to step down extra high voltages such as 60,000 to 110,000 volts to ordinary transmission voltages from 6,600 to 26,400 volts. The diagram (Fig. 24) shows the connections for a three-phase Star Delta bank for transforming from 110,000 volts to 13,200 volts.

The chief advantage of the use of Y connected transformers for high tension work is due to the fact that the current in the H. T. coils is greater and the mechanical strength of the conductor is therefore greater than in transformers built for Delta connection, also the voltage across the terminals is considerably reduced. Thus for a 110,000 volt system, 64,000 volt transformers are used. Furthermore the voltage to ground on the transmission line is only 64,000 volts whereas in the Delta system it would be 110,000 volts and hence there is less strain on the line insulators. On important systems it is necessary to have a spare transformer in case of breakdown to insure certainty of service.

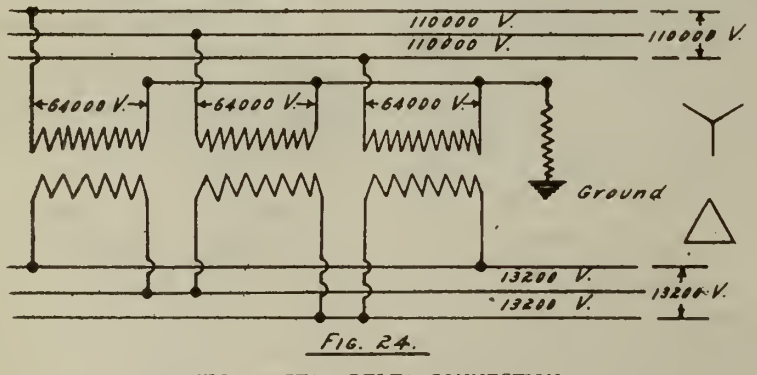

FIG. 24 STAR DELTA CONNECTION

(5) Open Delta

Open Delta, or V connection as it is sometimes called, is used on a three phase system where only two transformers are available or where one of the three transformers of a three phase Delta bank has been burned out. Diagram (Fig. 25) shows two transformers connected in open Delta both primary and secondary.

The voltage diagram of the secondary of this transformer bank is shown in the following diagram (Fig. 26):

The line a b (Fig. 26) represents the voltage across the terminals of transformers A and b c, the voltage across the terminals of transformer B which is 120 deg. out of phase with the voltage a b. The potential difference between terminals a, and c, will also be seen to be 220 volts and thus a true three phase current may be obtained with this combination of transformers.

In a combination of three single phase transformers in delta the combined capacity of the bank is three times that of a single transformer. By cutting out one transformer, we not only reduce the capacity of the bank to two-thirds of the former value, but it is still further reduced owing to the fact that unlike the three transformer combinations the current and voltage waves in the transformers are 30 deg. out of phase.

This may be explained as follows:

Assuming in the first place that we have a Delta connected bank of transformers supplying a three phase load consisting of a Delta connected motor. This may be represented by the diagram (Fig. 27).

As pointed out previously the triangle a, b, c, (Fig. 28) represents the voltage relations in a delta connected system.

Let the sides of the triangle represent the line voltages in magnitude and phase. If we are supplying a load at unity power factor, the load current, is in phase with the voltage. Let us start at the load and work back to the transformer bank. Draw b x, b y, and b z, equal to the load currents and in phase respectively with the voltages b c, a b, and a c. Thus x y, x z, and y z, represent the line currents in magnitude and phase and it will be noted that the line currents are not in phase but are 30 deg. out of phase with the line voltages even though the power factor is unity. In the transformers supplying the power to the line, however, the voltage and the current are again in phase. The currents b x and b z, which in the above diagram were combined to form the line current x z, being again split up into its component parts in phase with the transformer voltages. Now suppose transformer C to be removed, thus forming an Open Delta combin-

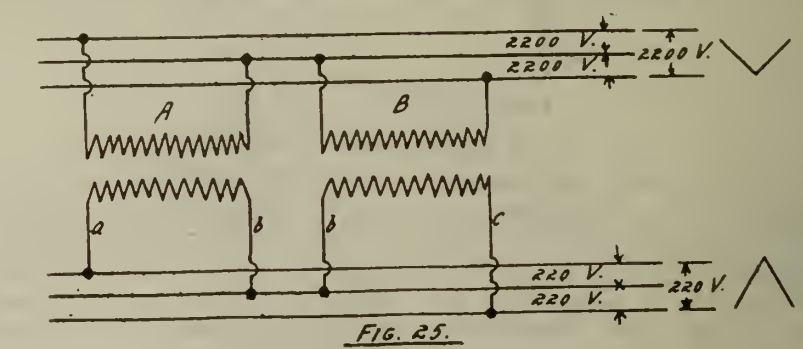

FIG. 25—OPEN DELTA CONNECTION

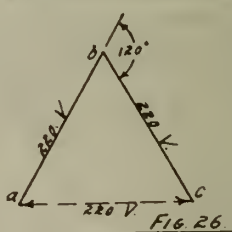

FIG. 26—VOLTAGE RELATIONS, OPEN DELTA CONNECTION

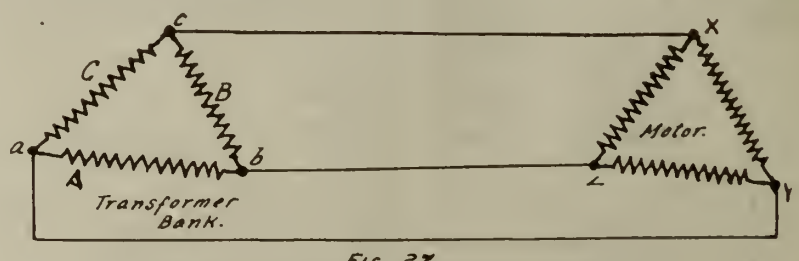

FIG. 27 TRANSFORMER AND MOTOR IN DELTA

ation. The current b z must be carried by the other two transformers in series. Transformer B for instance must carry its own current b x, and the current b z, the sum of these two currents being x z. Similarly the current carried by transformer A is y z. It will thus be seen that the currents in each of

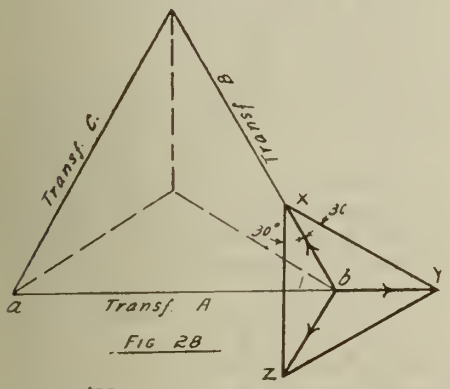

FIG. 28—VECTOR DIAGRAM

these transformers are not only increased by $\sqrt{3}$ or 1.732 times, but are changed so that there is a phase difference of 30 deg. between current and voltage in the transformer. It could not be otherwise, for the transformer currents are identical with the line currents and we have

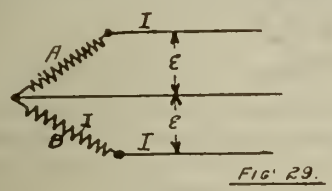

FIG. 29

previously shown that a phase difference of 30 deg. exists between line current and line voltage.

The amount of this reduction may be calculated as follows (Fig. 29):

The current in each transformer is I and is the same as that in the line, also the voltage E of each transformer is the same as that across each line wire.

Thus the capacity of each transformer is $\frac{E\ I\ (K.V.A.)}{1000}$ and the total load being transmitted over the line according to the well known formula is $\frac{1.73\ E\ I\ (K.V.A.)}{1000}$ so that the ratio of the capacity due to this connection is $\frac{2\ E\ I}{1000}$ to $\frac{1.73\ E\ I}{1000}$ 2 to 1.73 or 86 per cent.

Thus the capacity of two transformers in Open Delta is 86 per cent. of the rated capacity of the transformers and is 2-3 × .86 or 58 per cent. of the capacity of the total capacity of the three transformers in a closed Delta bank.

(6) Tee Connection

There is another method, by means of which a balanced three phase load may be taken from a three phase line by using only two transformers. This is called the Tee connection and is shown in Fig. 30.

This connection requires the use of two special transformers. Transformer A must be equipped with 50 per cent. taps—both primary and secondary and have all three leads brought out of the case. Transformer B must be equipped with 86.6 per cent. taps, both primary and secondary, with only two leads brought out.

The vector diagram showing current and voltage relations with the scheme of connections is shown in the following Figure 31.

In diagram (Fig. 31) a b, represents the voltage across transformer A—o c, represents the voltage across transformer B. Thus a b, a c, and b c, represent the line voltages. The line currents as before are 30 deg. out of phase with the line voltages and may be represented by x, y and z. Thus at unity power factor, the current in transformer B is in phase with the voltage while the current in one half of the winding of transformer A leads the voltage 30 deg. while in the other half it lags behind the voltage 30 deg.

The method of arriving at the proper voltage tap for transformer B is as follows:

The voltages across a b, and a c, are equal and 120 deg. out of phase and o a is one-half of a b, or a c. Therefore if o a, is designated as one then a c, equals two, and o c, must necessarily be $\sqrt{3}$ or 1.732 so that the relation between either a c, or a b, and o c $\frac{1.732}{2}$ =86.6 per cent.

The capacity of two transformers connected in T is not equivalent to the sum

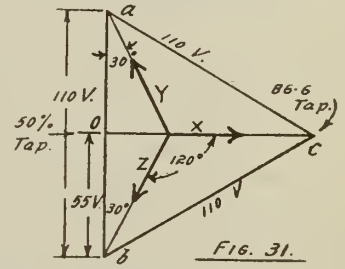

FIG. 31—VECTOR DIAGRAM TEE CONNECTION

of their rated capacities but is smaller since in the transformer A the current is 30 deg. out of phase with the voltage and only 86.6 per cent. of transformer B is used.

The k.v.a. in a three phase circuit is equivalent to $\frac{1.732\ E.\ I.}{1000}$

The k.v.a. in a T connection is $\frac{2\ E.\ I.}{1000}$ so that the transformers in a T connection will only carry 86 per cent. of their rated capacity providing they are similar transformers.

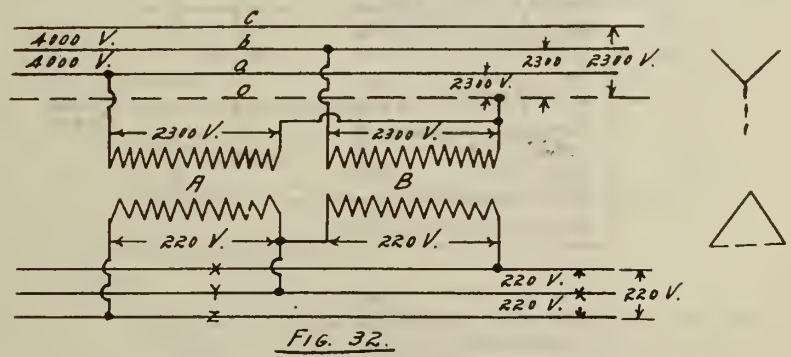

FIG. 32—OPEN Y, OPEN DELTA CONNECTION

(7) Open Y—Open Delta Connection

This is another connection which is coming into use particularly on 4,000 volt lines (2,300 volt Y) for use on small loads where the use of three transformers is not warranted. This connection, unlike the previous three phase connections, does not produce a balanced load on the line—in other words all the power from this combination is taken from two phase wires and the neutral. It is necessary to use three combinations of like capacity connected in rotation in order to secure a balance and all balancing current is carried by the neutral. Fig. 32 shows the scheme of connections.

It will be noted that in this connection, no power is taken from one of the primary lines.

The vector diagram of this connection is shown in diagram Fig. 33.

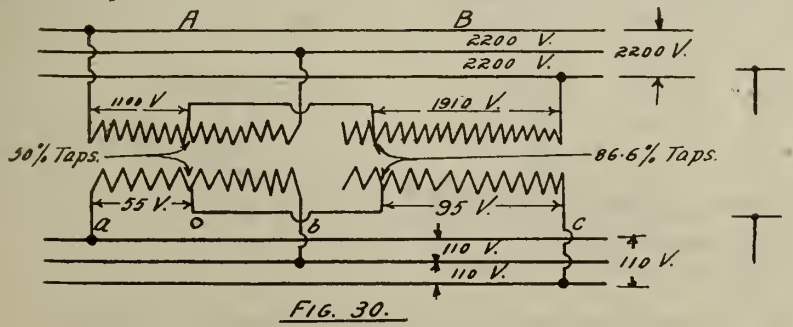

FIG. 30—TEE CONNECTED TRANSFORMERS

The voltage across the primary of the transformers is represented by o b, and o c, each equal to 2,300 volts and with 120 deg. phase relation. The line voltage b c, is 4,000 volts. The voltage induced in the secondaries of the transformers is in phase with the primary voltage, but in transformer B is in the opposite direction. On o c, mark off o y, equal to 220 volts and produce b o, to z, making b z,=220 volts. The voltage y z, is also equal to 220 volts and since these voltages are in 120 deg. phase relation we have a balanced three phase voltage on the secondary. As the current in the open Delta secondary is 30 deg. out of phase with the voltage, the capacity of this combination is 86 per cent. of the rated capacity of the two transformers or 58 per cent. of the capacity of three transformers connected Delta or Star.

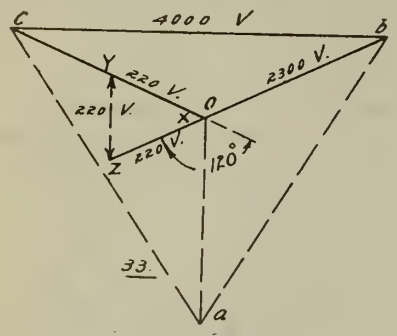

FIG. 33 VECTOR DIAGRAM, OPEN Y, OPEN DELTA CONNECTION

(8) Booster Connections for Three Phase Circuits

As pointed out previously in the case of single phase circuits, transformers may be connected in a three phase circuit for either bucking or boosting the line voltage. In a three phase circuit in order to get balanced voltage three transformers are necessay. These may be connected either Delta or Y as shown in Fig. 34.

Two transformers may be used as boosters on a three phase system which, however, introduces a slight unbalancing of voltages.

This method is shown in Fig. 35.

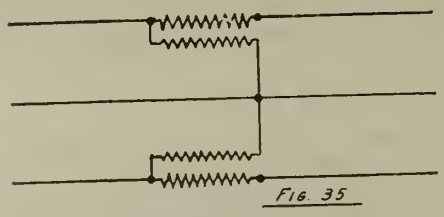

FIG. 35—BOOSTER CONNECTION

(D) Two Phase—Three Phase Connections

It is possible by means of two transformers to transform from two or three phase and vice versa. The system of connections ordinarily used for this purpe is called the Scott connection, although there are other schemes which can be used. The diagram of connections is given in Fig. 36 in which power from a three phase 2,200 volt circuit is stepped down to 220 volts and at the same time changed to two phase. Two transformers only are used, the Scott connection being very similar to the Tee connection.

For a Scott connection, the three phase side of the combination, whether primary or secondary, must be provided with special taps, one transformer being provided with a 50 per cent. tap while the other is provided with an 86.6 per cent. tap. It will be seen that the H. T. terminals of transformer A are connected to two of the three phase mains, and one terminal of transformer B is connected to the middle tap of transformer A and the 86.6 per cent. of transformer B is connected to the remaining three phase main.

The four secondary terminals are connected each to one of the four wires in the two phase mains. It is possible to effect a two phase—three phase transformation by means of auto transformers, the ratio of transformation being one to one. This will only work on a four wire two phase system in which the two phases are not interconnected. Suppose that power is supplied two phase and we wish to transform it into three phase.

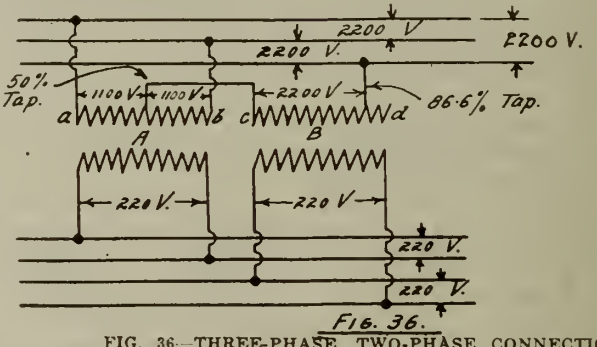

FIG. 36—THREE-PHASE, TWO-PHASE CONNECTION

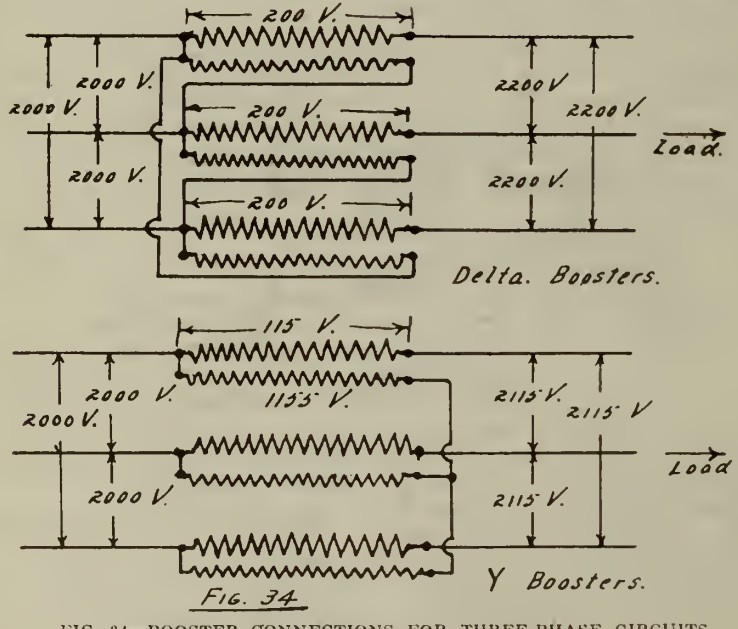

FIG. 34—BOOSTER CONNECTIONS FOR THREE-PHASE CIRCUITS

The diagram (Fig. 37) shows the manner of working this connection and diagram (Fig. 38) shows the voltage relations in this combination.

Two phase voltages are at 90 deg. phase relation with each other. If we impress one phase of a 2,200 volt two phase circuit across a b, and the other phase across c d,—c, being the middle point of a b, then the lines a b, and c d, in the above figure properly represent the voltage conditions both as to magnitude and phase relation. Now it is apparent that if a point e, be taken somewhere on the winding c d, such that a e, and b e, are equal to a b, that we would have a balanced three phase voltage, each voltage being at 120 deg. phase

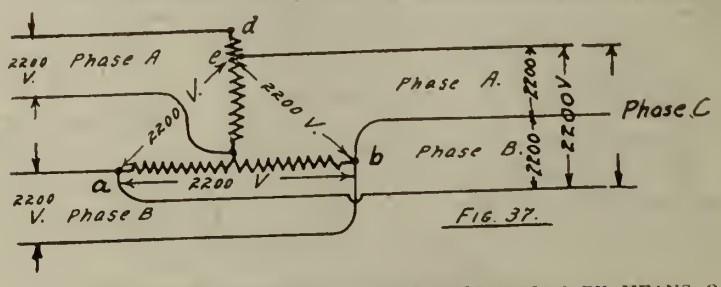

FIG. 37—TWO-PHASE, THREE-PHASE TRANSFORMATION BY MEANS OF AUTO-TRANSFORMERS.

relation with the other voltages. The exact location of the point c is found as follows:

a b, is equal to a c, or c d, and a c, is one half a b, therefore if a c, is equal to one, a c, must equal two and c e, equal

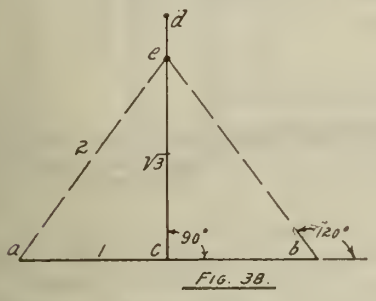

Fig. 38.

FIG. 38—VECTOR DIAGRAM, SCOTT CONNECTION

to $\sqrt{3}$=1.732, therefore the relation of the portion of the winding c e, to the whole winding c d, is 1.732 to 2 and $\frac{1.732}{2}$ =86.6 per cent. So that it is necessary for the winding c d, to have an 86.6 per cent. tap.

The relation of the current to voltage in the transformers in the Scott connection are similar to that of the T connection and hence the capacity of two transformers connected Scott is 86 per cent. of their rated capacity.

It is apparent that the Scott connection will work equally well in the reverse direction, i.e. with three phase power supplied will transform with two phase.

TALBOT BOILERS

Continued from page 68

and packing trouble is practically eliminated by using a special form of water cooled stuffing box. No cylinder oil is used within the cylinders, and long tests covering several years have proved that the wear is even less without the use of cylinder oil than with it in engines operated on wet steam.

Engine Control

The control is effected by an oil operated piston, both the reverse mechanism of the engine and the throttle valve being operated from any position in the boat where the control station is located or from various positions if more than one control station is installed. Four small pipes carry the oil from the piston at the control station to the oil piston on the throttle valve and reverse gear on the engine. This control is effected very much easier than any gas engine control yet devised, as no manual effort is required, there being no clutches, etc. The engine itself reverses and the control mechanism is perfectly balanced so that practically no power or effort is necessary in controlling the engine. The steering gear on our latest battleships is controlled in substantially the same manner as controlling the Talbot steam power plant.

The Canadian Letters Patent and exclusive rights to manufacture, sell, install, etc., Talbot contra-flow steam boilers and Talbot uni-flow engines, have been secured by C. L. Dixon, late works manager and production engineer of the P. Lyall and Co. munition plants. Mr. Dixon is now president and general manager of the Montreal General Tool Co., which firm is now manufacturing this new class of power equipment.

SOME POWER PLANT NOTES

By James E. Noble.

WHERE a water column is blown down the glass will show a higher level when the valves are closed. Some firemen who have not studied engineering and who do not ask questions have doubtless wondered why this is. The answer is easy. Hot water is lighter than cold. Before the glass is blown out the water has had time to cool and contract; after being blown out the glass is filled with very hot water.

Experiment has proven that if two tubes, one containing water at a temperature of 80 degrees Fahrenheit and one containing water at a temperature of 340 degrees, corresponding to an absolute pressure of 55.94 pounds are equal in diameter and enough water at the lower temperature is put into one tube to raise the water level 30 inches, and an equal amount of water, by weight, placed in the other tube at the higher temperature, or the temperature raised in the first mentioned tube to the high temperature, the level will be about three inches higher.

One thing which many plant owners do not seem to know is that ashes are a mighty bad thing to cover iron pipes with, unless black or galvanized wrought iron or steel pipes are laid in glazed tile pipe with cemented joints, or properly insulated from moisture in some other way, ashes placed around them will soon cause them to corrode. If hot water or steam is passing through the pipes the corroding process will be more rapid than if the pipes were cold. Go around among the outlying small plants and I venture to say that in many of them it will be noticed that ashes are dumped around on the ground under which wrought iron or steel pipes are laid. When these pipes corrode into holes they are removed and renewed. Perhaps the owner will rail against the makers of iron pipe, call them rogues and grafters, etc., and proceed to fill up the trenches containing the renewed pipes with a mixture of ashes and soil, mostly ashes. Dry ashes seem to have no injurious effect on pipes but add moisture and the "eating" starts.

The following point may have been overlooked by a few. In a cold water pump, and sometimes in a hot water pump the valves will last for many years. In time the valve stem holes get worn, or enlarged, so much that there is a great stoppage of water. This will be noticed generally in the greater speed of the pump to deliver the same amount of water as originally.

If the valves are taken out and the valve stem holes reamed out to a true circle, and pieces of brass tube placed on the valve stem, from the head to the thread, and the valves then placed in the stem, which is screwed back in place as usual, it will be noticed that the water delivery has been greatly increased.

RADIATION SHOULD BE PREVENTED

The loss of heat by radiation from boilers and their settings, and from steam pipes, may be very serious indeed, unless care is taken to keep it down to as small an amount as possible. In some parts of the country it is common to see boilers standing out of doors, with no protection, even in winter, except the roof over them,—the sides of the boiler shed often being entirely open to the weather, with little or no provision for shielding the boilers and piping from the cold out-door air. This is exceedingly bad practice, not only on account of the waste of fuel that it entails, but also because the chilling action of the air upon the heated metal gives rise to severe strains that shorten the life of the boiler, and sometimes lead to immediate rupture. Stationary boilers should always be properly housed in and covered, and portable ones should be enclosed by suitable coverings that will protect them from direct exposure to the air. Pipes conveying steam should also be effectively covered with heat-insulating material, to reduce the radiation and condensation as much as practicable. The loss of heat from the brickwork of the settings is best prevented by care in designing the settings.

OTHER STEAM WASTES

There are many other ways in which heat is lost about a steam plant through the waste of steam, and the engineer should always be looking for them, and he should remedy them at once when they are important enough to require attention. Steam jets discharging into the furnace of the boiler are sometimes used for improving combustion, and there is often no proper appreciation of the large amount of steam that is consumed in this way. Steam jets are also occasionally used for improving the draft, but except in locomotives, where it is impossible to provide the requisite draft by other means, this practice is too wasteful to be recommended. Tube cleaners that are operated by steam may be very wastefully used, and in applying these and other devices that consume steam, the fact that steam costs money should never be forgotten by the man in charge.

SAVING DRIPS

A great deal of heat is lost by the improper disposal of the water of condensation that is formed in radiators, pipe coils, and other steam-using apparatus. Drips of this kind can easily be returned to tanks, from which they can be pumped into the boilers and used as feed water.

Oil and Coal Compared for Steam Generation

How a Coal-Burning Setting Was Adapted to the Burning of Crude Oil With Considerable Advantage—Economical Operation Was Found to Result From the Change

By G. H. HOYLES

THE above heading may be of much interest to our northern engineers and works managers, as it is to others farther south, where oil is more plentiful. Recently it had great importance to a large munition plant in the middle West, incidentally to myself.

We were in the unfortunate position of not being able to obtain a guaranteed supply of coal at a reasonable price and quality, which compelled someone to get busy along other lines. We were using fuel oil as a heating medium for our heat treatment furnaces, which were on a large scale, compelling us to provide storage capacity for 80,000 gals., with pressure pumps, etc., for same. After several weeks' delay it was decided to use fuel oil under the boilers.

The battery was composed of two "Erie City" return tubular, 250 h.p. each and one B. & W. The Erie City boilers were eventually selected as the easiest to convert. The same type of burner as we were using on our heating and normalizing furnaces, with a few alterations we made in our machine shop, was fitted to boiler fronts.

The original bridge wall was taken out with the grate bars. A special floor was built (see sketch). The front end was at level of fire hole plate, extending back one-third the length of boiler, on an angle of 25°. This floor was constructed with openings for free air regulated by original ash pit doors, of a total space of 650 square inches, after quite a lot of experimenting.

Fire brick was used, obtained from an old boiler setting, which had been dismantled previously. Supports for the floor were made from 4-in. T iron; each end let into the side walls.

The burner, 1 for each boiler, was fitted to boiler front, 8 inches above fire-hole door. A hole was cut 6 inches diam. to allow front section of burner to enter, which, with the four 5-8 in. bolt holes used to bolt burner to boiler front, was all the cutting required.

The nozzle of burner, which had its oil outlet at same angle as floor, 25 degrees, was fan-shaped on a 2½ radius and 3 in. wide, with an ⅛ in. opening. This was ultimately reduced to 2½ x 1-32.

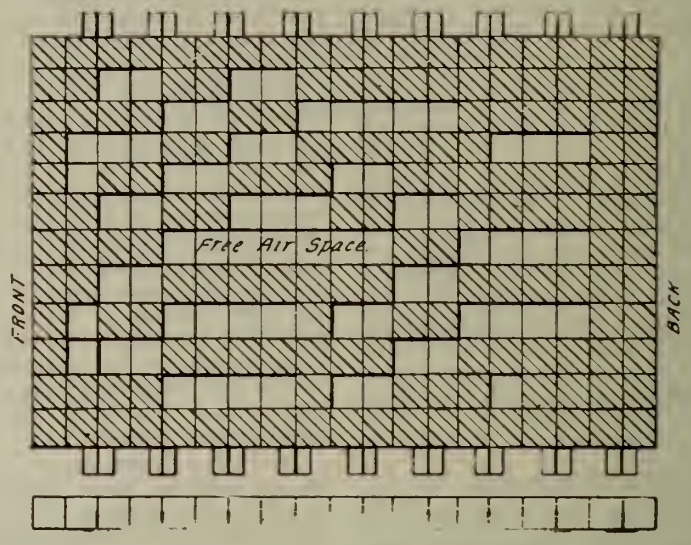
Oil of 18,045 B.T.U. per lb. was used at 80 lbs. pressure, with a 1 lb. air pressure supply delivering air through a 3 in. diam. pipe around the nozzle; end of 3 in. pipe was 2 in. behind end of oil pipe, so as to drive oil forward in a fine vapor. This air supply was dispensed with, excepting when boilers required forcing for any reason.

On a 6-hour run, with 110 lbs. steam, and supply pipes empty and ready to be filled from supply which had been weighed, 14 lbs. of water (also weighed) per lb. of oil, were evaporated to steam at 110 lbs. Temperature of feed water was 198 degrees average. The steam was used for a large heating system, all on the ground floor, returns flowing to boiler room.

This was considered a great improvement on what it would have cost for coal, allowing market price for coal and oil at that time, Nov. 15th, 1918.

It was afterwards decided to place the same type apparatus in a large works which the same firm were contemplating farther east.

Should like to hear how this compares with other experiences along same lines, as in a few years I firmly believe there will be much more oil used than is used at present time.



DESIGN OF CHECKERWORK BRICKWORK

OPEN BOILER-ROOM DOORS

In the summer season it is often necessary to keep the boiler-room doors open, in order that the room may be comfortable for the attendants; but in the winter, especially in our northern latitudes, care should be taken to prevent the entrance of unnecessary quantities of cold air, because this increases the loss of heat by radiation from the boilers and piping. It must not be forgotten, however, that it is always necessary to admit to the boiler room a quantity of air sufficient to compensate for the air that enters the ash-pits and goes up the chimney or stack. The draft will be impaired if the doors and other openings into the boiler room are all kept tightly closed, because the pressure in the boiler room will then become reduced by the action of the chimney until the flow of air into the ash-pits may be checked to a notable extent. Air is sometimes drawn from the boiler room by fans, for warming other parts of the plant. This is poor practice, for several reasons. The air of the boiler room is often charged with dust and ashes, and moreover as the fans act in direct opposition to the chimney, they are likely to check the draft very seriously unless the doors and other openings into the boiler room are left wide open.

COVERINGS FOR PIPES AND BOILERS

The coverings that are used to check radiation from pipes and boilers should have good heat-insulating properties. Non-conducting coverings should be of such a nature that leaks from pipes or from the roof of the boiler house will not damage them seriously, and they should not be made of materials that are likely to char from heat. In selecting them, attention should be given, not only to the cost of the material, but also to its heat-insulating power, as determined by experiment.

Coverings upon pipes that convey steam or hot water under pressure should be applied in such a way that they can be removed readily for repairs or inspections, particularly where the pipes enter fittings of any kind. In the event of a leak at these places, it will then be possible to examine the pipe and make the needed repairs at materially less expense than would be involved if the covering were put on without regard to this contingency.

Our Question Box

Question.—How does the water circulate in a Robb-Mumford boiler?

Answer.—The boiler consists of two cylindrical drums; the bottom drum contains the furnace at one end and numerous small flue tubes at the other, all of which are surrounded with water and connected together by water legs; the lower drum is inclined about one inch per foot, which promotes the circulation of water. In operation the water and steam bubbles circulate upwards and to the rear of the lower drum, passing up the rear neck (or water leg) to the upper drum; they then circulate down the front neck to the lower drum. The upper drum is called the steam drum.

Question.—What is the difference between a single-ended and a double-ended Scotch boiler?

Answer. — The single-ended Scotch boiler has a furnace at one end only. The double-ended Scotch boiler has a furnace at each end, and resembles two boilers placed back to back. The double-ended boiler is lighter, cheaper, and occupies less space than two single-ended boilers.

Question.—In what respect does a flush-tube vertical boiler differ from a submerged tube?

Answer.—This refers to a vertical boiler. When the tubes extend to the upper head of the boiler their upper ends passing through the steam space above the water line, it is called a flush-tube boiler. In a submerged-tube boiler the tubes do not extend above the water line and there is a smoke-box between the upper tube sheet and the chimney.

Question.—What is a wet-bottomed fire-box boiler?

Answer.—A boiler in which the furnace is entirely surrounded by water. It is a common construction in semi-portable constructions.

Question.—What is the object of the mud-drum of a Babcock and Wilcox boiler?

Answer.—The mud-drum collects a considerable portion of the solids contained in the feed water and is blown off at intervals.

Question.—I notice with many fire-box boilers that the inner side of the furnace sheets are liable to crack at the lap joints. Is there any reason for this, and is there any remedy?

Answer.—The sheets are liable to crack at this point owing to the difference in temperature between the fire side and water side of the point which sets up local stresses. Bevelling the furnace side of the lap and using countersink rivets occasionally remedy this fault.

Question.— Is there any difference in strength between concave and convex heads?

Answer.—The convex heads are stronger, design being similar.

Question.—What is the Adamson ring joint?

Answer.—A joint formed in a built up furnace flue by flanging the sections and riveting them together with a finished ring between them.

SOME OLD TIME RECIPES AND POWER PLANT RECIPES

As a rule, the engineers in charge in office buildings and institutions have to attend to repairs on the plumbing, heating, and other such work. The following information will prove of value to many readers, and it is information not generally known.

Years ago I used the receipt below for making a powder to cement together marble slabs which had been broken; many such slabs are used around water closets and other places. Up to date I have not seen any article better, or as easy to make.

Make a saturated solution of alum by dissolving as much alum as possible in some water; soak some plaster of paris in it; then bake it hard and dry in an oven, and grind it to a powder.

To use it take the needed quantity of the powder and mix it with water, like plaster, and apply it to the edges of the broken marble or slate. It sets very hard and it can be given a high polish; also, it can be made any color desired by using mineral colors in the powder. It requires quite a few words to describe this wrinkle, but it requires very little work to make the powder. One broken slab repaired will pay for the little trouble of making the cement many times over.

Another good thing I used in former and present days is a disinfectant. Why use such horrible smelling stuff, such as chloride of lime, or expensive chemicals, such as caustic soda? One pound of nitrate of lead, which is a very cheap material, will make several barrels of fine disinfectant.

To make a small quantity, take half a dram of nitrate of lead and dissolve it in a pint of boiling water; also dissolve two drams of common salt in 10 quarts of water. Mix the two together and when it is settled, pour off the clear liquid, which is a saturated solution of chloride of lead.

Some of this liquid poured down a water closet, sink, or drain, or onto any decaying or offensive objects, will at once sweeten the fetid atmosphere. A cloth saturated with the liquid and hung up in a room will produce the same result.

No doubt many of your readers have come across the street vendor who sells "Magic solder." It is used by holding a candle under a hole in a tin or copper utensil, which has been scraped clean around the hole on one side, and rubbing the solder over the hole, filling it up. The solder is simply a mixture of two parts tin, one part lead and one part bismuth. However, a slightly different mixture, namely, 1 part tin, 1 part lead and 2 parts bismuth, is a solder melting at a temperature of 200 degrees Fah. and makes an excellent agent for soldering automatic sprinklers, using venice turpentine or white rosin as a flux. This solder will neither harden or weaken with age. In using the solder on sprinkler heads it is best to use a blow torch, as the use of a copper soldering iron on this solder is apt to slightly change the melting point.

And last, here is a mighty simple, but good tip.

Do not continually keep sweeping the dust cement from a cement floor. Give such a floor a brushing over with boiled linseed oil and convert your dusty cement floor into a dustless one.

The Future Fuel

A COUNTRY rich in water power will have an enormous advantage over those not so fortunate when coal becomes scarce in the distant future, but waterpowers in themselves will not be able to supply the demand for energy and other sources will have to be called into play. The power of the wind and tides might well be used and greater than these, solar energy. The deserts of the tropics will become vast power generating areas and possibly manufacturing centres drawing their raw materials from the near-by countries.

One other form of energy which may become available in the dim future exists in all matter and the possibilities latent in the atom made known to us through radio-active substances are vast indeed but almost hopeless in accomplishment so far as the present is concerned.

The problem of the world's future supply of energy is a fascinating one in many ways and it is altogether likely that before a great many years it will become more serious than fascinating.

The coal resources of the world are by no means inexhaustible and in fact are being rapidly depleted in many areas at the present day. Our present methods of using coal are wasteful in the extreme and it is only a matter of a few years probably until enormous steam plants are established at the mines in conjunction with coking plants wherever possible. Our methods of heating will likely undergo considerable modifications also and the central heating plant will likely be quite common. This plant will also squeeze the last mite of power out of the fuel before turning the steam into heating mains. The present trend in steam power plant design clearly indicates that much higher steam pressures will be in common use before long, that is pressures ranging from 300 lbs. to 750 lbs., or even higher.

Buying Second Hand Equipment

ACCORDING to an item in the Humboldt (Sask.) "Journal" of recent date a new boiler is needed for the town plant, and the engineer in charge of the plant also recommends that a condenser should be added to the equipment.

In fact, the situation is that the plant will soon have to be shut down for repairs unless a new boiler is added.

The town council has heard the situation outlined, and has been informed that a condenser should increase the efficiency of the plant some twenty-five per cent.

Prices have been secured on new boilers that run from $2,650 up, and a condenser, it is said, would cost around $4,000. Of course, there are variations from these figures.

But the council has wind of an outfit that can be secured in Saskatoon for much less money. The boiler is said to be on the market for $500, while the condenser is to be had for $800. And so it is that the heart of the town goes out to the Saskatoon outfit.

Of course, there would be an immediate saving. Between the figures quoted for new and used outfit there is a spread of $5,350. But what of it? It may be that the Saskatoon outfit is a regular bargain, in good shape, and put on the market under exceptional circumstances. If so, then the town stands to gain.

But why should a place of any size go into the market for second-hand equipment for a municipal power plant? Buying a second-hand boiler and a second-hand condenser is, as a general thing, doubtful policy. That states the case mildly. If the tubing has defects which come to the surface after put in use again, the difference in price can soon be absorbed in the re-tubing of the equipment.

Humboldt would be much better advised to send their specifications directly to a list of responsible firms in Canada, and ask for quotations on a new outfit of lines that are known to be good.

Councils often make mistakes of this sort. They imagine that a boiler is a boiler, and a condenser is a condenser. The fact that the thing has boiled before or condensed before is not taken into consideration.

The belief grows with men who have an expert knowledge of such affairs that it is good policy and good financing to go into the machinery or power transmission market with a requisition for new material that carries with it the backing and guarantee of the people who make it.

The Operators' Point of View

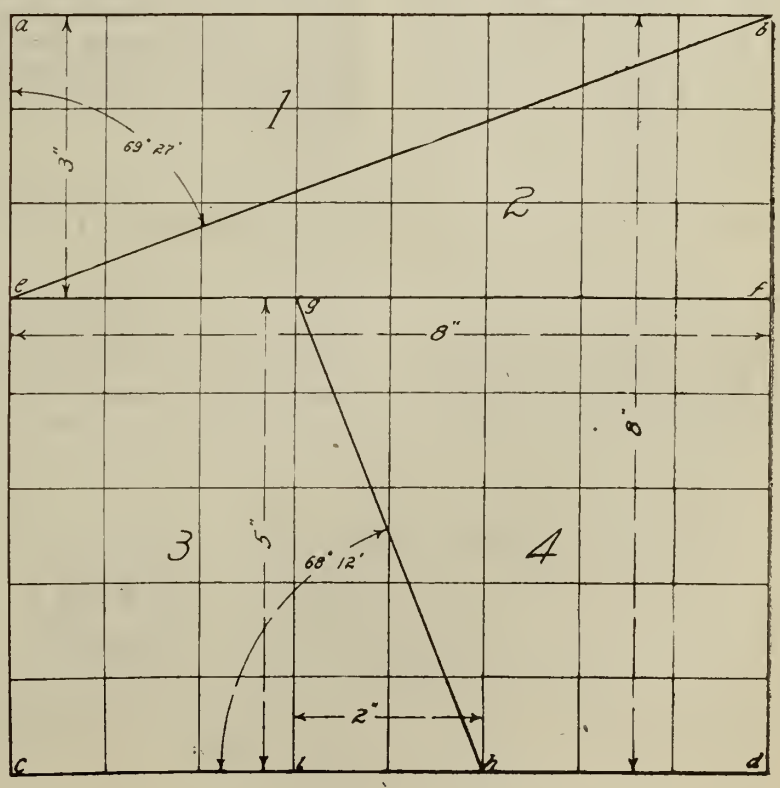
SOME HINTS ON THE OPERATION OF WOOD-FIRED BOILERS

AMONG sawmill plants located in the country or on a timber limit, and where the fireman lives or boards in a house close to the mill, it is sometimes convenient for him (if he is using slab wood for fuel) to allow the fire to burn to coals when getting near closing time, and, with the water shut off (first making sure it is high enough in the boiler so that he can afford to) let the heat of the fire all go to making steam for the engine; then, when leaving, after closing down for the day, turn on the injector and let the boiler fill up while he is away to tea. This economizes wood by making it unnecessary to fire quite so hard for a time before stopping, and also avoids waste of escaping steam (from the safety valve) as a result of heat produced by a bed of wood coals existing on the grates after hours. Obviously, this is only practised where the proportions of boiler and injector are such that the attendant will have plenty of time to eat and return before the boiler becomes too full. Generally the injector pipe enters and takes steam from the dome, and if the attendant is unexpectedly delayed, the boiler may become filled up into the said dome, thus necessitating more blowing down before raising steam again than is necessary for sediment only. To avoid this occurring, if the injector pipe is tapped into and takes steam from the top of the boiler, instead of from the dome, and if a long thread, say 3 or 4 inches, is cut on the inner end of the piece of pipe entering the boiler and this pipe then screwed into the boiler as far as it will go, the injector cannot then fill the boiler further than to near this pipe, for then water will begin coming down the injector steam pipe and the injector will begin to work spasmodically—putting much water out at the overflow. Wet steam is bad for an injector, as it tends to wear the jets, therefore this spasmodic action should not continue any longer than can be avoided. The remedy? Attach to the steam valve of the injector an adjustable sprocket rim with chain guide and chain. To the chain attach a vessel capable of hoiding water, and have a pipe bringing water to it from the injector overflow. As the vessel gets heavier with water it will descend, thus closing the valve. The adjustment should be such that the vessel will come to rest on a support just as the valve closes and before it jams. If this valve and the check valve are in good condition and proper strainers on the water supply pipe to prevent fine dirt reaching and lodging under the check valve, then the remaining valves may safely remain open until the said attendant arrives. This device is not meant as something to be called into use regularly; it should, like the plug in the crownsheet of locomotive type boilers, be ready to act if occasion so demands, yet occasion should not be permitted to demand it. Where the slab wood was from timber which did not burn well, I have known firemen to help themselves considerably by thus utilizing the injector during the noon hour as well as after closing for the day. If this gets past the W.P.B., probably old hands accustomed to coal will consider this bad practice, but I am not advocating this method for plants using coal. Years ago I fired where either coal or wood could be had, the company had a supply of each. I asked for coal and got it during my entire stay. The man who worked on the same job, but the opposite shift, preferred the wood, asked for it, and got it. I have seen men accustomed to coal take charge of steam outfits burning wood, and when they banked their fire they would leave their furnace doors open. With wood, the furnace doors should be shut as much as possible at all times while there is a fire on, whether the fire is banked or not, and if the fire is banked to hold for hours the ash pit doors should also be closed tight (unless the wood is wet or otherwise very bad, in which case the draft is regulated accordingly), but the furnace doors should, in any case, be left shut. This is correct practice with wood, but you know how long a coal fire would remain in the desired condition if banked in this manner. With the difference in fuel can reasonably come an occasional difference in methods of operating. Circumstances alter cases.

J. E. McCORMACK.

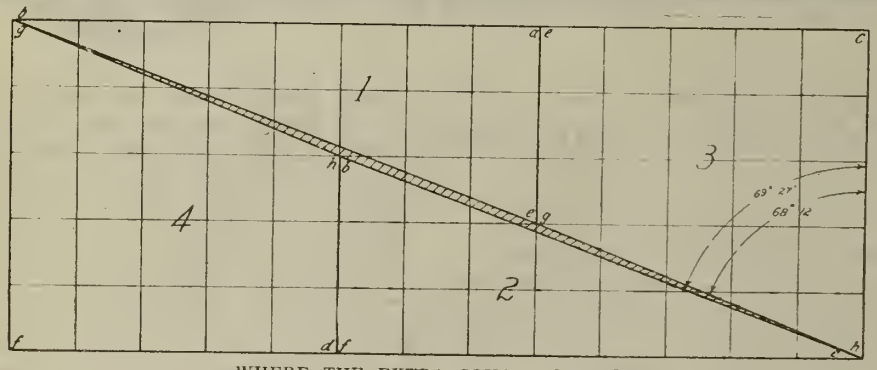
AREA—64 OR 65 (?) SQ. INCHES

One of our readers has again brought up the mythical problem of making "something out of nothing," namely, that of obtaining an additional unit of area by the rearrangement of a certain num-



SQUARE TO BE DIVIDED

ber of units. The query is, that if a square is composed of 64 square inches, 8 inches on a side, and the same is cut as indicated in Figure 1, and then arranged into a rectangle 5 inches wide by 13 inches long, that an area will be obtained equal to 65 sq. inches, or a "gain" of 1 sq. inch. This problem has been given much publicity, largely as a result of the query arising from those who may see the re-arranged pieces placed in position, with a slight change in the angle, so that the figure has the appearance of an unbroken rectangle containing 65 sq. inches.



WHERE THE EXTRA SQUARE IS GAINED

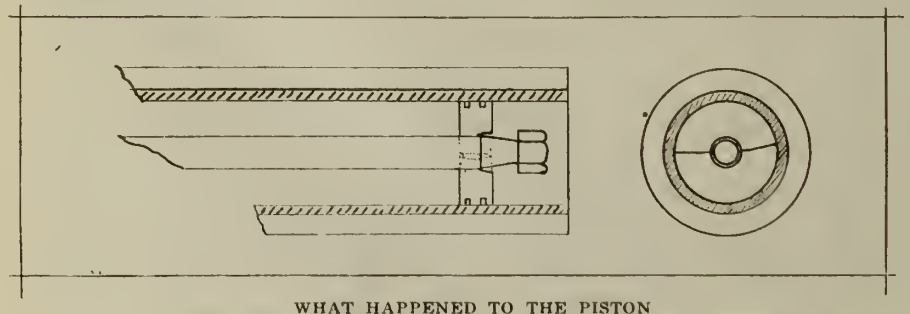
The original square of 64 sq. inches, is divided as shown in Figure 1, The sections 1 and 2 are identical and each forms a right triangle 8 x 3 inches; the sections 3 and 4 form two equal trapezoids, the parallel sides of which are 3 and 5 inches. It can therefore be readily seen that as the total area is 64 sq. inches, no possible arrangement of said sections will produce an area greater or lesser than the initial area. Figure 2 shows the rearranged sections that provide the area of "sixty-five"? sq. inches. When these pieces are cut out and placed together the diagonal line from b to h can be brought close together so that a casual glance will give the impression that an extra sq. inch has been "found." Or when this is drawn to puzzle the minds of the uninitiated the diagonal can be drawn from one corner to other. It will be seen however,—and can easily be proven with a drawing board and pencil,—that, when the sides b—c and f—e are parallel, there is a long narrow space produced along the diagonal as shown in Figure 2. The area of this slit can be calculated and proven to contain the sixty-fifth sq. inch.

The length of the diagonal e - b, Figure 1, can be found by extracting the square root of the sum of the squares of the two sides; $\sqrt{3^2+8^2}=8.544$ inches. The length g-h is found in the same way, g-i-h being the right triangle. $\sqrt{2^2+5^2}=5.385$ inches. The approximate length of the diagonal in Figure 2 will be 8.544 + 5.385=13.93 inches. The angle c-h-g equals 68 degrees 12 minutes and the angle a-c-b equals 69 degrees, 27 minutes. Therefore the acute angle of the diagonal space in Figure 2 is 69 deg. 27 min., minus 68 deg. 12 min., or 1 deg. 15 min. The zinc of this angle is .02181 and therefore the parallel portion of the narrow space will be .02181 x 5.385=.117 inches approximate. The area of the two tapered ends will then be 5.385 × .117=63005 inch, and the parallel section in the middle will be 3.159 x .117=.3696 inch, and the total area of the space will be .63005+.3696=.99965 inch. The slight variation from the exact sq. inch is due to the elimination of decimal places. It will be seen from the foregoing that the increased area is one of imagination only.

A DAY OF REST IN THE POWER PLANT

By T. H. FENNER

A SERIOUS and expensive breakdown occured to an 11"×9"×14" high speed tandem compound engine under my charge in a peculiar manner. The accident occurred on a Sunday, when the regular engine room attendant was not on duty. As a matter of fact, no one was in the engine room at the time, the fireman on duty in the boiler room being under orders to come up and look at the oiling arrangements from time to time. To understand what happened we must have a glance at the boiler room, where the cause of the accident originated.

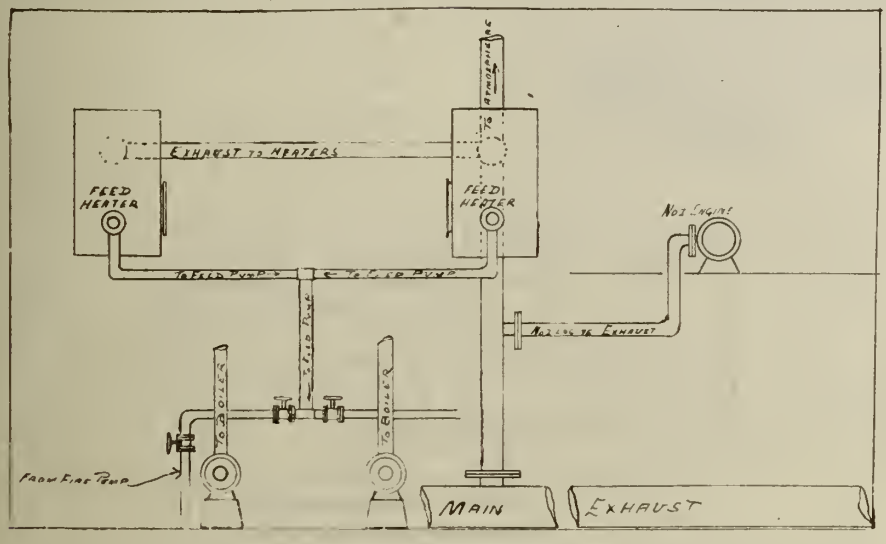


WHAT HAPPENED TO THE PISTON

The feed pumps took their water from overhead open heaters, of the Webster type, discharging through economiser to boilers. There was also a direct discharge to main feed leader direct, by passing the economiser, and also a direct discharge to an auxiliary header, as shown. The suction pipe from heaters to pump came down to a T between the two pumps, and branched off to each pump. There were also two independent suctions on each pump connected to hot and cold wells. On one of these suctions a connection had been made from the discharge of the fire pump for washing out boilers, and an emergency boiler feed. A branch was tapped off the auxiliary header at each boiler to connect the valve of the turbine hose for washing out. When washing out the fire pump was used, discharging through the feed pump suction, through the pump, and auxiliary header. The boiler room staff had stringent orders never to touch this fire pump valve, the engineer on duty in the power house being the only one authorised to make the connection. The reason for this care was apparent, as if the valve from the fire pump was opened and the suction from the open heater left open at the same time, the discharge from the fire pump would have clear access to the heater and from this to the whole exhaust system.

The day that the accident happened being a Sunday, in the ordinary course of events nothing would have been running. However a 50 h.p. armature had burned out on the Saturday morning, and the millwrights and electricians had been working Saturday afternoon and Sunday morning and were ready to try the motor after dinner Sunday. This would mean, if the repairs were O.K., about ten minutes running. Being anxious to know if everything would be alright for Monday morning, I decided to go down to the factory myself. The regular day engineer had been instructed to come in after dinner to run the engine as required, but as he had not shown up I started up myself, made the switchboard connections, and saw that the forced lubrication was alright. I told the fireman where I was going, and warned him to come up at intervals of not more than ten minutes, and look at the engine. I expected to be all through before he came up twice. However, some minor troubles developed in connection with the motor and shafting. A man was sent over to the engine room to see how things were and he reported everything alright. We got ready to start the motor again, and it started up this time perfectly, but after running about five minutes the motor started to slow down and the lights to dim. I started for the engine room on the run, but about half way there was met by the fireman, who informed me in quite a disinterested way that No. 1 engine had "gone to h—." He also volunteered

the information that there was a lot of water in the basement. Arriving in the engine room, I saw a tangle of oil pipes, and the broken crank case lying on the floor, and at the same moment an ominous cracking broke on my ears. Coupling this with the fireman's statement of the leak in the basement, I made a rush for the feed pump, finding what I expected, the valve from the fire pump open, and the heaters and exhaust system flooded. The leak in the basement was the excessive overflow from the heaters backing up the water seal from the sewer. The next thing was to look at the water gauge to find the water just bibbing in the bottom nuts of the glasses on the two boilers that were working. I began to reconstruct things a bit in my mind, and then proceeded to



PIPING LAYOUT

catechise that picture of injured innocence, the fireman. The evidence being so complete, he could not deny opening the valves, but hedged a bit about the reason. However, I had a good idea of that, too, and on putting it up to him, he admitted the soft impeachment. He began the course of events by neglecting to watch his gauge glass, and when he did look, found the glass full, but how much more he knew not. However, he promptly stopped the feed pump, neglecting to shut the checks on the boilers. He then resumed his paper, being anxious to see how Foch was making out. Presumably he found the news to his liking, for when he next looked the water was about half glass. He congratulated himself on his excellent judgment in stopping the pump, and thought it would be all right now to start it up again. Here he struck a snag. The boiler checks not being dead tight, when the pump stopped some leakage occurred from boiler to pumps, resulting after a while in the pumps and heaters getting good and hot, too hot to handle water. Deciding that here again was a case for a good man to use his own judgment, he decided to pump some water through from the fire pumps, achieving the double purpose of feeding the boilers and cooling off the lines and pumps. He started up the fire pump, opened the discharge through the feed pumps, and left the main suction open. The water in the boilers did not rise, but it did somewhere else, and his ears were soon assailed by numerous strange noises. At the same time his gauge glass lamps started to lose their brilliancy, and it crept into his mind that something was wrong. He went up to the engine room just in time to hear a crash, and had then decided to go and get advice. His view of the matter was that it was decidedly unjust to spoil any poor man's Sunday by involving him in a series of untoward happenings that kept him in a state of nervous tension. Not having time to discuss the matter fully I went to ascertain the damage. I found both the crank pin and crosshead gib straps sheared off, the brasses themselves broken in several pieces, and all the oil piping twisted and broken. The cast iron crank case was also broken, though this was a detail. This was the outer damage. Next thing was to look for the internal troubles. The H. P. cover was removed and an attempt was made to move the piston ahead.. It was apparent at once that something was jammed, and jammed hard, as the hammer rebounded as though from an anvil. It was decided to take the nut off the end of the rod, and a spanner was brought for the purpose, but at the first application the end of the rod and the nut came away together, and it was evident that the rod had been ready to break. We then found that the piston came off the taper surprisingly easy, and after removing the piston from the rod a tentative tap with a hammer was tried on the end of the rod with the same result as before. The next step was to open up the L. P., and this achieved, the trouble was at once evident. The L. P. piston was cracked across, the crack being open from ⅛ in. to 3-16 in., and the piston had been forced over the taper into the parallel part of the rod, jamming on the walls of the cylinder. The only way it could be removed was to drill holes all round the boss and break a piece out, letting the piston come down on the rod, and relieving the pressure. The piston was then taken out in halves. The repairs necessary were new piston rod, new low pressure piston, new connecting rod end brasses, gibs, straps, cotters, and bolts complete, and oil piping, guards, etc., all of which was done at the factory.

Cause of the Trouble

What had happened was as follows: The water from feed pump had backed up through open heaters till they filled up to overflow level. The overflow took care of some of the water, but the level still rose till it came to the exhaust steam opening. Entering this it dropped down to the main heating exhaust and travelled along to the building. Presumably about this time the engineering genius in the boiler room, finding he was getting no water in the boilers, speeded the pump up a bit. There was some back pressure on the engine by now but the water had not yet reached the level of the cylinder. However, shortly after it did, with the results as named. When the final smash occurred the engine was just coming to the back centre. She must have been considerably slowed down from her normal 260 R. P. M., and was probably running about half that. The L. P. piston met a solid wall of water, and the energy of the fly wheel was enough to force the rod through the piston, splitting the piston and jamming everything hard and fast. The fly wheel still possessed considerable energy, the whole of which was applied to move the crank ahead, against the resistance of the immovable L. P. piston. The weakest parts were evidently the straps in crankpin and crosshead, and these parted. The fly wheel evidently made a few revolutions after this, as the connecting rod was thrown back near the front cover, and pieces of the bearing boxes were in the crankpit and on the floor, while the oil piping gave mute testimony of what it had gone through. The shock of the sudden stop on the H. P. end of the rod had to be absorbed by the piston nut, and this had evidently been too much for it. The metal had given, and the piston had loosened in the taper and was ready to let go at the first movement. This shows what can happen through one man's carelessness, and the guilty one should be susceptible to a more drastic punishment than being discharged as in these days being discharged holds no terror for the average fireman.

UNIFORMITY OF PRACTICE

It is conducive to economy to have the boiler-room practice as uniform as possible in all respects. The water level should be kept at a fixed point, except when it is temporarily lowered by opening the blowoff from time to time. The steam pressure should also be maintained at a steady value, and an approved routine should be established for every detail in the room. When this is done the work will go on almost automatically, and in the best way possible. Any errors or omissions on the part of the attendants will also be more quickly observed.

Progress in New Equipment

3-WIRE METERS

AT the present time, when great attention is being given to conservation and standardization, the new direct-current, 3-wire, service type watthour meter, just placed on the market by the Sangamo Electric Company, Springfield, Ill., is attracting much attention.

This meter consists simply of 2 standard 2-wire elements placed side by side in a common base and registering their K.W.H. on a common recording train, so that the sum of the revolutions of the 2 elements will be properly added and indicated on the K.W.H. dial of the meter. This is effected by means of a very simple but ingenious differential gearing within the recording train, so that no matter what load there may be on one element as compared with the other, the total revolutions of the two elements will be accurately added and recorded. Even with one element fully loaded and the other one without load, the registration is as accurate as though each element were recording on a separate train.

This arrangement of meter elements and train is not new, but has been given a thorough and successful test on similar ampere-hour meters built for use with storage batteries on submarine vessels of the U. S. Navy during the past two years. The only difference between these very successful ampere-hour meters for submarines and the present 3-wire D-5 service type meter, is in the fact that the driving elements in the ampere-hour meters have permanent magnet fields instead of shunt energized fields of the watthour meter.

As will be seen from Fig. 2, each element of the new 3-wire meter is a standard 2-wire element including the light load adjustment, the arrangement of damping magnets, and in the case of meters over 10 amperes capacity, the arrangement of internal or external shunts. As shown in diagram, Fig. 3, and from the arrangement of the elements it will be apparent that this meter achieves for the first time the requirements of a true 3-wire direct current meter; that is, one which will measure and record accurately the load on either side of a 3-wire distributing system, no matter whether the other side is entirely dead. For example, if the fuse in one outer line of the system is blown or purposely withdrawn, the element connected in the other side will record ac-

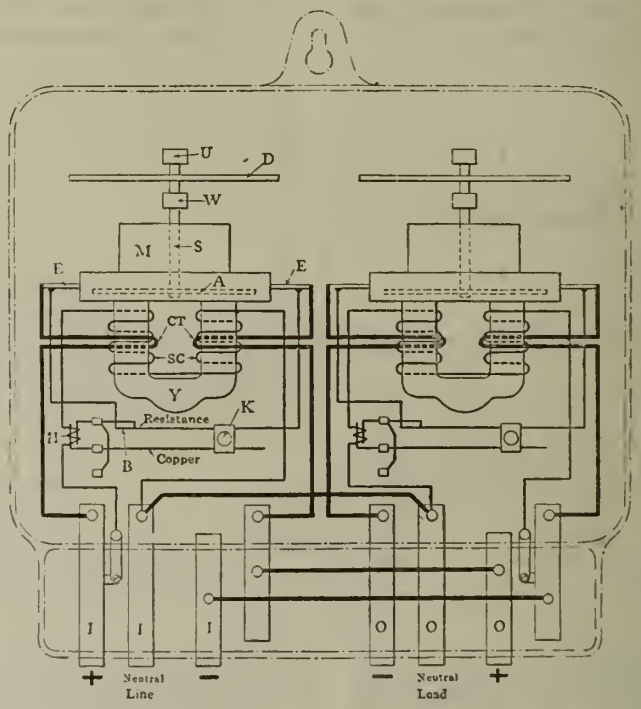


DIAGRAM OF CONNECTIONS

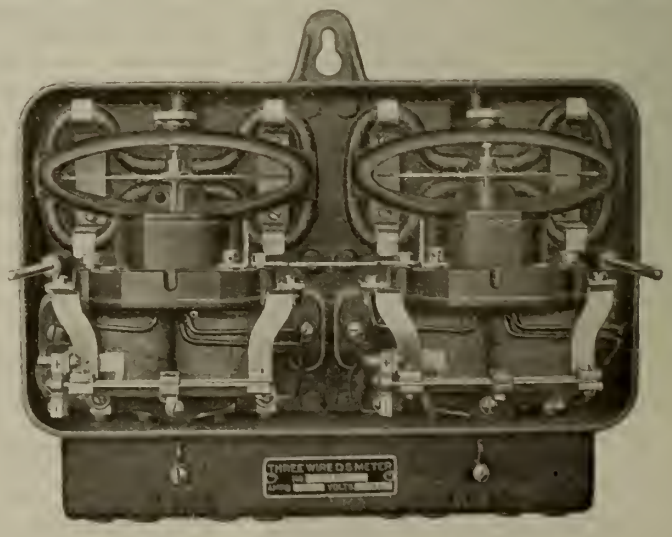
EXTERNAL VIEW



SHOWING ARRANGEMENT OF MECHANISM

curately the load on that side, as its potential circuit and measuring circuits are entirely independent of the side which is open. If the neutral fuse is blown or withdrawn, the two potential elements remain in series across the outer lines so that the meter will continue to record any load that may pass through it between the outer wires with the neutral open. Under widely unbalanced conditions of voltage between the outer lines, this meter will record with a degree of accuracy which is impossible with any former 3-wire direct current meter having a single potential element connected either between one outer line and the neutral, or between the two outer wires. As shown in the diagram, the elements are so connected through an ingenious interchange of connections within the terminal box itself that the load wires from and to the line pass in and out of the meter in regular succession; no crossing over or interchanging of leads being required.

The recording train is held on a bracket connecting the two motor elements, shown in Fig. 2 with the train removed, and absolutely correct meshing of the two worm wheels on the train, engaging with the two elements, is obtained by a system of locating rear bearings of the worm wheels similar to that used in the standard 2-wire meter. The train is held in position by a simple locking device operated from the top front so that it may be readily removed for purpose of inspection and calibration of the elements.

In calibrating, each element is considered and tested as a standard 2-wire meter without respect to the other element. For this reason, an absolutely perfect balance of the two elements may be secured in minimum time and effort by the tester.

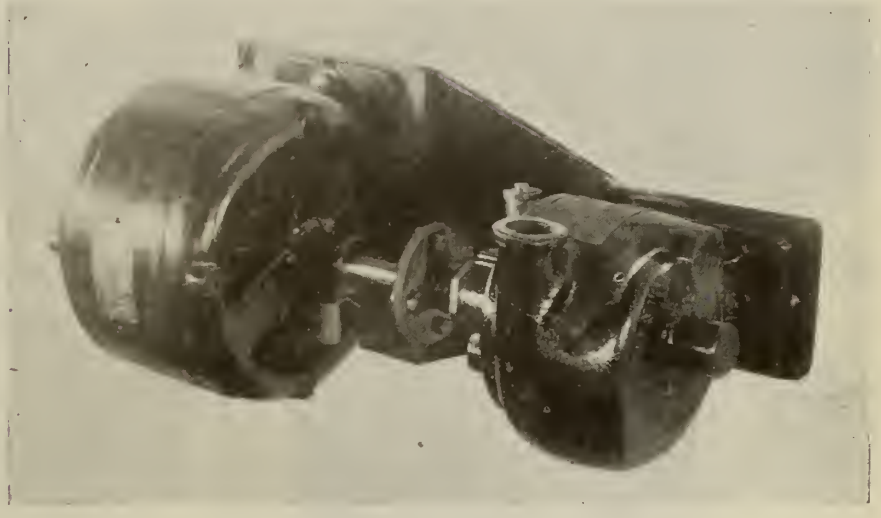
A NEW FULFLO PUMP

The Fulflo Pump Company, Blanchester, Ohio, has placed on the market a line of direct connected motor driven pumps. These pumps are designed for use in connection with high-class motor driven machine tools, oil circulating baths and for supplying batteries of machines with cutting oils or compound.

They are all centrifugal in type, but retain their prime without the aid of valves or other mechanical means, each pump being provided with a priming chamber and having both intake and outlet located at the top, which makes it impossible for the pumps to lose their prime. The impellors are of the semi-enclosed type, and are supported by a bearing at either end of the impellor shaft. The thrust is on the suction side of the impellor and is taken care of by a hardened steel thrust collar on the impellor shaft which thrusts against the nose of the bronze bush supporting the impellor shaft on the suction side of the pump. The thrust at this point is very slight as most of it is taken up by the coupling between the pump shaft and the motor shaft.

The main pump bearing also forms the pump gland and is of cast iron. The lubrication of this bearing is taken care of by a sight feed oiler which feeds into a pocket completely surrounding the bearing.

The shaft is of hardened and ground steel. The packing used is the flexible metallic type and is guaranteed not to cut the shaft. The life of this pump is exceptionally long as the impellor, the only internal pumping part, does not depend on any contact fits for its pumping efficiency. Standard pumps have cast iron bodies, covers and impellors, but may be furnished in brass or bronze when so desired.

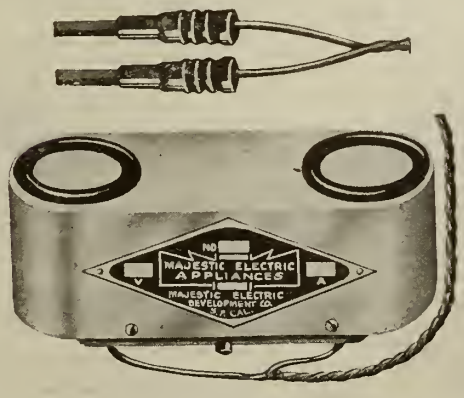


NEW FULFLO PUMPING UNIT

THE MAJESTIC DETERMINATOR

Doubt always causes loss. In every case of doubt there is a loss of time, and in most case of doubt the loss of time is accompanied by a more or less serious loss of money. The foregoing applies with more force to electrical work than to any other, as most of the expensive and dangerous burnouts are caused by doubt—doubt as to whether the current is A. C. or D. C.

When motors, transformers or any instrument operated by electricity are to be installed, the first thing necessary is to find out what class of current the building is supplied with, and for this use the Majestic Electric Development Company, San Francisco, have developed the Majestic determinator. Formerly there were but two ways of determining the character of the current supplied: first, by "feeling the juice," which should never be done, as it is always extremely dangerous. Second, by asking the central station, which puts them to considerable trouble and places an unnecessary responsibility upon their shoulders, which they are not willing to assume. This method is uncertain, as the central station may be supplying that particular building with both alternating and direct current.



DETERMINATOR FOR A.C. AND D.C. CIRCUITS

The Majestic determinator is an instrument as simple in operation as it is certain. To operate it, all that is necessary is to place the plugs to the wires or terminals, press the button at the bottom of the determinator, and if the current is direct, the letters D.C. will instantly appear within one of the circles at the top of the determinator; if the current is alternating, the letters A.C. will appear within the other circle. The brilliancy of the light back of the letters A.C. or D.C. tells whether the voltage is 110 or 220.

The plugs attached to the determinator are knife blade type and are so constructed as to render short circuit or shocks impossible.

With this instrument, all open fuses and circuit breaks may be accurately determined. Broken wires or coils, as well as bell and lighting circuits, may be accurately tested with it.

Every wirer, trouble shooter, electrical engineer, superintendent of buildings, or, in fact, anyone having anything to do with electricity, may use one of these instruments to advantage.

The Majestic determinator has no delicate or moving parts or fuses, therefore, is not liable to get out of order. It is 4 inches long, 2 inches high and 1½ inches wide, weighs 7 ounces.

This device is being manufactured and marketed by the Majestic Electric Development Company, 656-658 Howard street, San Francisco.

STRAIN
YOUR OIL

Use Twin Oil Strainers and insure a continuous supply of clean oil for your burners.

Fuel oils commonly contain some solid matter which must be removed from the oil before it can be used with any degree of satisfaction. To do this, it is necessary to use some kind of a strainer, so why not use the Twin—a strainer that can be cleaned without shutting off the supply?

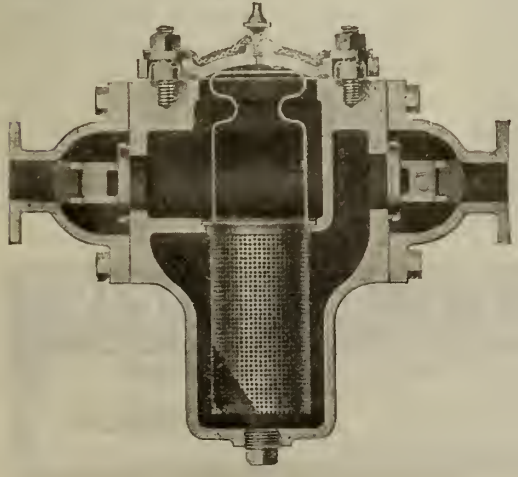
THE TWIN OIL STRAINER

gives the same service as two single strainers, but it is more convenient to operate, it requires less space for installation and it does away with all extra valves and piping necessary to connect up. These are the features that led to its being used in Submarines and Destroyers now being built for the United States Navy and in cargo boats now being built for the United States Merchant Marine.

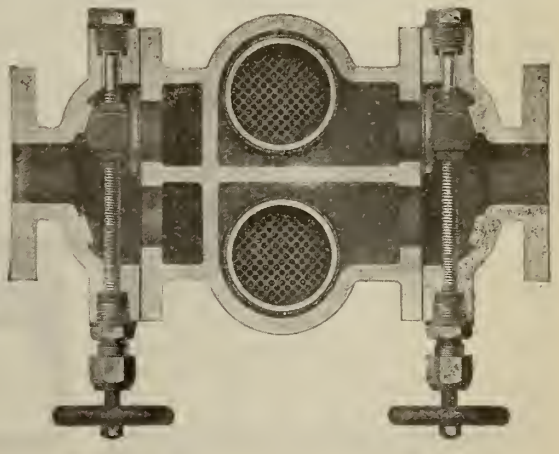
Sizes range from 1 to 5 inch. (2½ inch and larger sizes have flanged connections). Basket mesh 1/64 inch or larger. See Bulletin "AA" for details.

ELLIOTT COMPANY, 443 Diamond St., Pittsburgh, Pa.

The oil enters the Strainer at the left and empties into and passes through the straining basket, then up and out at the right. All solid impurities are retained in the straining basket.



When a basket is clogged, the valves are shifted to direct the flow of oil into the clean basket, which is in reserve. The compartment containing the dirty basket is then opened up, the basket removed, cleaned and replaced, and held in reserve until the basket then in service needs cleaning.



Terry's Commercial Manager Visits Canada

Very few manufacturers in the metal and engineering trades are as well known, or serve such a diversified class of trader as the house of Herbert Terry & Sons, Ltd., Redditch, England.

From a one man genesis in 1855 the business has grown, until to-day it employs between 1,200 and 1,400 workpeople, and embraces more than 60 highly-organized departments. Both technically and financially the firm has a high reputation, also being successful in maintaining cordial relationship between employer and employee.

The firm is producing every known kind of metal spring and numerous other light metal articles. A big line of goods for motor garages, lock springs, flexible shafting, etc., are included in the lines which will be shown by Mr. Ernest Clarke, the commercial manager of the firm, who is visiting Canada for the purpose of demonstrating his firm's ability and desire to serve Canadian manufacturers and traders.

Mr. Clarke is able to quote for any kind of spring needed and to give much valuable advice based on his technical knowledge of the business.

Mr. Clarke can be addressed at any of the offices of The MacLean Publishing Co.—Advt.

BOOK REVIEW

Steam Engine Troubles by H. Hawkens, $2.50—The Norman W. Henley Publishing Co., New York.

A practical treatise on the troubles which are common to the operation of various types of steam engines. With the great number of different designs of engines in use it is a somewhat difficult matter to determine the reason why things go wrong with certain parts and to prevent trouble and to remedy it when it does occur. In the present work the troubles which the principal parts of steam engines are subject to are described, good design is contrasted with bad, the most suitable material for certain parts and the best construction is pointed out. The advantages and disadvantages of many designs are discussed. The directions given for correcting existing evils are easily understood. The principal considerations in the building of foundations, setting of templets and lining up an engine are given with a complete account of how to erect an engine. Directions are given for lubrication valve setting and testing, also how to locate trouble with an indicator, and what adjustments are to be made on new engines and maintained on old ones. Speed regulations are also treated of and simple rules for calculating safe pressures of main bearings, stresses in flywheels, strength of cylinder walls, etc., are given which enable an engineer to find out whether the engine he runs is constructed on sound principles or not. The various parts of an engine such as cylinders, valves, piping and separators, throttle and emergency valves, pistons, frames, bearings, connecting rods, etc., are dealt with in detail, a separate chapter being devoted to each one. This work should prove quite welcome to those having the operation of stationary engines in their charge.

Graphical and Mechanical Computation, by Joseph Lipka, Ph.D., John Wiley and Sons, Inc., New York; the Renouf Publishing Co., Montreal. Price $4.00.

A book written as an aid in the solution of a large number of problems which the engineer, as well as the student of engineering, meets in his work. In the opening chapter the construction of scales is developed and leads to a discussion of the principles upon which the construction of various slide rules is based. The second chapter develops the principles of a network of scales, showing their application to the use of various kinds of co-ordinate paper and to the charting of equations in three variables. Engineers have recognized for a long time the value of graphical charts in the lessening of the labor of computation. Among the charts devised none are so rapidly constructed, nor so easily read as the charts of the alignment type. Chapters III, IV and V give a systematic development of the construction of alignment charts; the methods are illustrated by charts for a large number of formulae. It is the writer's hope, as expressed in his preface, which we quote, that the simple mathematical treatment employed in these chapters will serve to make the engineering profession more widely acquainted with this time and labor saving device. Many formulae in the engineering sciences are emperical, and the value of many investigations is enhanced by the discovery of laws connecting the results. Chapter VI is concerned with the fitting of equations to emperical data. Chapter VII considers the case where the data are periodic, as in alternating currents, sound waves, etc. Where emperical formulae cannot be fitted to experimental data, further computation can be made by interpolation, differentiation, and integration by the methods developed in the last two chapters. Numerous illustrative examples are worked throughout the text and exercises are given at the end of each chapter. While a preliminary knowledge of mathematics is essential to the complete understanding of the subject matter of this book, it places in the hands of the designing engineer a powerful means of simplifying the calculation of problems arising every day in structural, hydraulic, power plant, mechanical and electrical engineering. The treatment adopted throughout is concise and well arranged.

Electro-Metallurgy, Electrolytic and Electro-thermal Processes, By Eric K. Rideal, Bailliere, Tindall and Cox, London.

The rapid development of applied chemistry in recent years, accelerated by the recent war, has brought about a revolution in all branches of technology. A series of books, of which the present publication is one, is being prepared by the publishers as an aid to the further development of industrial chemistry throughout the British empire. This series will give a general survey of the particular portion of the science dealt with and each volume is complete in itself. The present volume is divided into eight main sections dealing with electrolysis in aqueous solutions; electrolysis in fused electrolytes; the electrolytic preparation of the rare metals; electro-thermal processes; carborundum and oxysilicides of carbon; the carbides; electro-thermal nitrogen fixation by metals and metallic compounds, and iron and the ferro-alloys.

In an introduction to the above sections the problems relating to the ample supply of power necessary for electro-metallurgical operations are dealt with and interesting figures relative to comparative costs of power production by present methods, hydro-electric, coal, gas and oil are given. In Great Britain, where waterpowers are scarce and coal plentiful, the cost of producing power by the latter would seem to be sufficiently low to warrant the establishing of electro-chemical plants using it as fuel. The metalliferous resources of the British Commonwealth are also dealt with in the introduction.

In the section devoted to electrolysis in aqueous solutions the winning and refining of copper is thoroughly taken up and special mention is also made of the use of colloid addition agents in electro-

CONDENSED ADVERTISEMENTS

FOR SALE — CANADIAN WESTINGHOUSE Motor—Type C. Constant speed, 100 h.p., 225 ampere per terminal, 2 phase. Full load speed 580, alternating 720. Box 150, Power House. (p3h)

W. J. WALL, 134-136 BLEURY ST., MONTREAL
(Canadian Representative)

lytic work. The other metals treated of in this section are zinc, cadmium, gold, silver, nickel, lead, antimony, bismuth, tin, cobalt and cobalt nickel alloys. In general this section may be said to be an exhaustive summary of present day practice.

In the section devoted to fused electrolytes, the preparation of sodium potassium, lead zinc, aluminum and other metals is dealt with. A portion of the book which is of considerable interest deals with the preparation of the rarer metals which are finding increasing application in modern industry. The section on electro-thermal processes deals with the smelting of and reducing of the metallic elements from their ores and also with the preparation of graphite and other electric furnace products.

Carborundum, carbides and the fixation of atmospheric nitrogen are also considered and an important part of the contents is related to the iron and steel industry.

As a reference aid to the metallurgist engineer or chemist interested in electrometallurgy this publication should find considerable usefulness and the excellent bibliography which is incorporated at the end of each section is of considerable assistance to those wishing to make further investigation.

The value of the work is greatly enhanced by the incorporation of much material in the nature calculations as to energy requirements for electrolytic and electro-thermal processes.

Forging, by John Jernberg, The American Technical Society, Chicago

The art of blacksmithing is an ancient one and for centuries was the only method-working profession. Very little improvement has been effected in it up to comparatively recent times. In the last few years the adoption of new types of steel has made considerable advancement necessary in the art of forging and also in the allied art of heat-treating. The author states that this book was written for the bringing up to date of the machinist's knowledge concerning the art of forging in its more modern aspect. One chapter describes mechanical details, materials and equipments, and goes into the various types of forges, furnaces, annealing ovens, and power tools which are used. Forging operations are next taken up and the major portion of the book is devoted to this particular subject, welding, upsetting and other forging operations being all dealt with. Heat treatment and its effect on the physical properties of steel is an important subject and is covered in a simple and able manner.

CATALOGUES

Buckeye Products Company, Cincinnati, Ohio, have issued their general catalogue number 7. This book contains 400 pages and is a reference work on foundry tools and appliances. Practically everything which is necessary to the successful operation of a foundry may be found in the pages of this book, and a list of reference books is included which may be purchased through the Buckeye Products Company.

The Morse Chain Company, Ithaca, New York, for which Jones & Glassco, Montreal and Toronto, are the Canadian agents, have issued publication Number 16, entitled "A Chain of Evidence." This publication is one of a series and deals particularly with the small power drive. The book is replete with illustrations and is of interest and of useful reference for those who have to deal with the transmission of small amounts of power.

The Crouse-Hinds Company of Canada, Limited, Toronto, have issued a four page folder called "Condulet Suggestions 64." This folder describes the use of their condulets and the arranging or the charging of storage batteries on the train lighting sets. In the installations the condulet is mounted on a concrete pedestal which both facilitates a plugging and insures against the condulet being frozen in or covered with snow during the winter.

The Goldie & McCulloch Co., Galt, Ont., have recently issued a catalogue on rotary jet condensers and vacuum pumps. This firm have obtained the rights to the Rees-Roturbo pumps and condensing equipment and this catalogue deals with the various types of condensing equipment which they are prepared to supply. Condensers in general are treated of. Condenser plant economies and the economy of high vacuum are shown. The Rees-Roturbo jet condenser is treated of in detail, its design being gone into thoroughly, and features of installation being dealt with in a very thorough manner.

The Graton and Knight Manufacturing Company, Worcester, Mass., have issued a very complete catalogue descriptive of the lines of belting which they manufacture. The first few pages are taken up in the description of the plant and of the various portions of the hides which go to make up the finished belt. The various grades of belting are taken up next and each one of the different classes manufactured by the Graton and Knight Company are described in detail. Various types of belt drives are treated of and much valuable data is given regarding the proper calculation of belting problems and the care of the belts themselves.

The Bureau of Mines, Washington, have recently issued Technical Paper 191 dealing with central station heating. Briefly stated, the paper sums up the manifold extravagances of utilizing about 15 per cent. of the heat valve of the fuel, allowing the remainder to go to waste, mainly in the condenser cooling water. This percentage is true of the most efficient plants of to-day. A method that promises at once to increase the community value of such stations is worthy of consideration and the central station heating offers a favorable solution. The development of central station service is dealt with, methods of computing costs and rates to be charged are also gone into thoroughly.

The LONG Patent Steam Trap

Automatically drains jacket kettles, separators and steam mains. Nine hundred to 1,500 feet of one-inch pipe isn't beyond its ability. Also used with splendid success in drying room systems.

Only One Movable Part

Works against 1 and 200 pounds of pressure—no possibility of freezing. Has two outlets so it can be installed in any position.

Circular gives full particulars.

Write to-day.

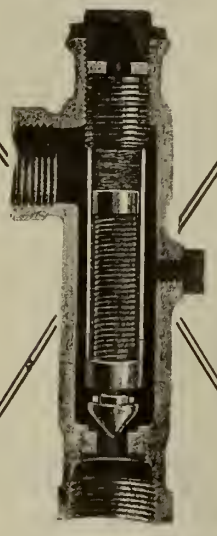
NON-CORROSIVE
CYLINDER OIL
MANUFACTURED ONLY BY
E. H. KELLOGG & CO.
NOS. 242-244 SOUTH ST. NEW YORK, U.S.A.
FRICTION LOSS

An overload is often a necessity. But it is hard on an engine. To successfully carry an overload so that there will be no after effects on the engine a very careful selection of your oil should be made. An oil that is not free from impurities will cause a greater wearing on the bearings, a great friction loss will occur. You will need to fire the boiler more often because the engine will be harder to run. In this manner you lose out. You work harder, have larger operating costs, and less power all because of your oil. Do as a great many Canadian engineers have done—give Kellogg's "Non-Corrosive Cylinder Oil" a trial. Absolutely pure. Write us regarding it.

E. H. KELLOGG & CO.,
New York, U.S.A.

No Delay No Bother
No Trouble
Ready for
Immediate Delivery

STEAM TRAP
SARCO



Is as readily installed as it is quickly supplied. No pit—no foundation—no expensive preparation. Because of its simple form and unique construction SARCO can be placed

Any Place Any Position
Any Angle

whether the pressure be low or high—2 lbs. or 200 lbs.—can be applied to your pipe line as easily as a coupling or an elbow—along the stretch, in the bend—*anywhere—any point needed.* SARCO is an efficient steam trap as easily inserted as a cork in a bottle. Do you wonder that several hundred thousand SARCOS are in use!

You won't wonder if you accept our offer of a trap on 30 days free approval.

and representatives in all principal cities.
Canada, Peacock Brothers, Montreal.

The Goldie and McCulloch Co., Galt, Ontario, have issued a very attractive catalogue on the Rees Roturbo pump, for which they have secured the manufacturing rights for Canada. The Rees-Roturbo pump has proven highly efficient and is widely used in Great Britain, Canada, and the United States, the high efficiency and self-regulating features proving particularly attractive. The literature, which has recently been published by the above mentioned firm, goes into the design of this pump very fully, and makes very interesting reading, the fundamental principle of the pump itself is very clearly explained. and the manner in which the problems connected with variation of head in either the suction or delivery are dealt with is clearly shown. The various types of single and multi-stage pumps are featured and dimensions and other information given concerning their design.

WESTINGHOUSE NEW ANNUAL CATALOGUE

The Westinghouse Electric & Mfg. Co. of East Pittsburgh, Pa., has issued a complete catalogue in which all of their electrical supplies are listed. In compiling the catalogue every effort was exercised to make it of the greatest convenience to purchasers.

The catalogue is made up of 1,264 pages of description pertaining to the products of the company and a score of other pages contains a complete cross index, and index to style numbers, and a table of "Approximate Cost Multipliers," which enables one to figure the approximate cost of all supplies listed.

Although the book is called a catalogue, it contains a vast amount of information of a technical and engineering nature. Practical suggestions for the use of many kinds of apparatus for the transmission and utilization of electric power are given.

It is planned to issue this catalogue annually. The publication of this catalogue is quite noteworthy, as it is the first book of such a nature published by an electrical concern having the wide diversity of products sold by the Westinghouse Company.

NEW PUBLICATION

The double-helical speed-reducing gear, as used for stepping down from the high speeds of steam turbines to speeds suitable for ships' propellers, direct-current generators, large centrifugal pumps and fans, rope and belt drives, etc., was first introduced about twenty-five years ago by the late Dr. De Laval. This type of speed-reducing gear has subsequently been developed and refined by the several companies bearing his name, particularly for large size units, by the De Laval Steam Turbine Co., of Trenton, N.J.

That company has now issued a 32-page catalogue describing standardized geared turbine units for marine service. The gain in fuel economy of the steam turbine over the reciprocating engine is stated to be approximately 25 per cent. The geared turbine weighs about half as much and occupies less than a third of the cubical space required by the engine. It is also more accessible and easier to repair, the expense for supplies and attendance is considerably less.

The new publication describes the details of construction of turbines and gears and also various turbine-driven auxiliaries, including lighting sets, circulating pumps, boiler feeders, etc. A new development is the centrifugal pump for the continuous purification of the oil used in the turbine and gear bearings and on the gear teeth.

DESULPHURIZATION OF BENZOL FOR MOTOR USE.

It is now possible by using a new method of desulphurizing benzol to make it more effective in competition with sulphur-free petrol. The portion of sulphur present as thiophene—about 30 per cent. of the total can be eliminated by washing with concentrated sulphuric acid, such as is required in the making of pure products, and the real difficulty is to get rid of the carbon bisulphide, which remains unaffected by the washing process, and of which the crude spirit contains on the average about 0.96 per cent. After numerous experiments a process was finally evolved and embodied in a patent by which the benzol is washed with caustic soda solution at a temperature just short of its boiling point. Sodium thiocarbonate water, and sodium carbonate are formed in the following proportions:—

$$6\ NaHO - 3\ Cs_2 = 2\ Na_2CS_3 - 3\ H_2O - Na_2\ CO_2$$

The caustic soda is prepared in the usual way from soda-ash and lime, but of higher strength than usual—aiming generally at a density of 26 deg. Twaddell, corresponding to approximately ten per cent. of NaOH. The charge of benzol forerunnings is blown into the mixer, which is a cylindrical tank fitted with an agitator having a series of arms radiating from a central shaft, a small reflux condenser (to return any vaporized benzol) and a heating coil. Steam is turned on full for about ten minutes, the agitator started. and the caustic run in. The agitation is kept up for about two hours. by which time the caustic has become exhausted; the contents of the mixer are then allowed to settle for some twenty minutes and the spent liquor is run off. The following particulars give details of a washing:

First wash—Caustic soda. 715 gallons. 27.5° Tw., 10.74 per cent of NaOH. Sp. Gr. after run 0.892. CS_2 3.57 per cent. — 59.55 per cent. reduction.

Forerunnings charged to mixer. 1,241 gallons. Sp. gr. 0.907. CS_2 8.83 per cent.

Second wash—Treated spent liquor from first wash, 550 gallons. Sp. gr. after run 0.885. CS_2 3.57 per cent. reduction. Total CS_2 removed 95.51 per cent.

The liquor from the second wash is again revivified. and used for partly washing a succeeding charge.—M.E.

III IMPORTANT THINGS
TO CONSIDER ABOUT
A SEPARATOR

I. THE PLAN—Is it sensible, will it work, no matter how large the Separator or how well made?

II. THE SIZE—Is it big enough regardless of plan, will it hold a good dose of water?

III. THE CONSTRUCTION—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

Sweet's Separators

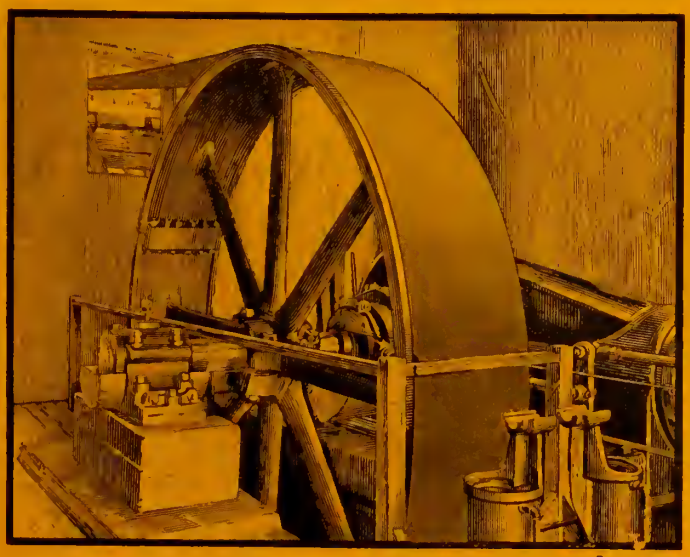
GRATON AND KNIGHT



GRATON AND KNIGHT

Nature's Contribution to Power

30-inch Neptune Double Belt, 91 feet long, driving mill of J. C. Halsema Mfg. Co., Jacksonville, Fla. This belt has been in operation five and one-half years, and is in as good condition as when first installed. It has given satisfactory service at an overhead charge of $2.17 per week, or a cost of five mills per horsepower per week

It's the right material in the right place. Nature provided that material, worn originally on the back of a steer. A steer hide is *naturally* tough, strong, pliable, elastic. All of those characteristic virtues are retained to the right degree in Graton & Knight Standardized Tanning. That tanning is done to meet fixed requirements.

Leather stands hard usage. It has a hull-dog frictional grip. It keeps on taking the punishment of main drives and the side-slapping of shifters—and then comes back for *more*. Good belting must have tractable pliability. It must be firm. It must stretch and come back when required. It must be easy to slice and repair. Nothing beats leather for these characteristics. No belting beats Graton & Knight Standardized Series Leather Belts.

Every Graton & Knight Brand isn't recommended for *every* drive. The work to be done determines the belt to be used—that is the G. & K. Standardization idea. Power transmission requirements are confined to a few classes. There's a standardized belt for every class. The Neptune Double referred to above is one of them. It's the Standardized Belt for use wherever dampness or water is present or where belting is subjected to exposure and rain, snow and other unfavorable climatic conditions; and for excessive loads.

Many of the best belted plants ask us to specify the belting for every *pulley drive*. Try the plan yourself. Then, when buying, call for "Graton & Knight—Brand or equal." This won't commit you to buying our belts. It will put your buying on the one basic consideration—the work to be done.

Write for information about Standardization as applied to Belting.

Dominion Rubber System Belting is Better Belting for Every Purpose

There is yet to be found a process, condition, use or industry in which belting is required that the Dominion Rubber System's belting engineers have not successfully and efficiently served with some type of our Belting.

If you have a problem for which there is no parallel, our technical experts will undertake to solve it without charge, and produce, if necessary, a special type of belt to satisfactorily meet your requirements.

Nearly every factory, mine, quarry, paper or flour mill, grain elevator or railway shop, is using our Belting as a satisfactory part of its equipment—some of the largest users specify it exclusively.

Our **Dominion Friction Surface Belting** will out-serve, at lower cost per horse-power, any belt made—because it is built up to the highest quality standard—by the oldest, largest and most highly specialized rubber organization in Canada.

An important factor in the service of Dominion Rubber System Belting is in placing the right type of belt where it will produce maximum efficiency—this is primarily due to our Dominion-wide service branches, through which the free advice of our belting engineers is available to every user of belting.

As one of these service branches is within 'phone distance of you, put it up to our experts to get you out of any difficulty that concerns belting.

Becoming a Bigger Man

WHAT is the difference between some men you know and others known to you? Why are some men earning $3,000 a year and some $30,000? You can't put it down to heredity or better early opportunities, or even better education. What, then, is the explanation of the stagnation of some men and the elevation and progress of others?

We are reminded of a story. A railroad man, born in Canada, was revisiting his home town on the St. Lawrence River. He wandered up to a group of old-timers who sat in the sun basking in blissful idleness. "Charlie," said one of the old men, "they tell me you are getting $20,000 a year," "Something like that," said Charlie. "Well, all I've got to say, Charlie, is that you're not worth it."

A salary of $20,000 a year to these do-nothing men was incredible. Not one of the group had ever made as much as $2,000 a year, and each man in the company felt that he was a mighty good man.

Charlie had left the old home town when he was a lad. He had got into the mill of bigger things. He developed to be a good man, a better man, the best man for certain work. His specialized education, joined to his own energy and labor sent him up, up, up. To put it in another way: Charlie had always more to sell, and the world wanted his merchandise—brain, skill and ability. Having more to sell all the time, he got more pay all the time.

Charlie could have stayed in the old home town; could have stagnated like others; could have been content with common wages. In short, Charlie could have stayed with the common crowd at the foot of the ladder. But Charlie improved himself and pushed himself, and this type of man the Goddess of Fortune likes to take by the hand and lead onward and upward. Almost any man can climb higher if he really wants to try. None but himself will hold him back. As a matter of fact, the world applauds and helps those who try to climb the ladder that reaches towards the stars.

The bank manager in an obscure branch in a village can get out of that bank surely and swiftly, if he makes it clear to his superiors that he is ready for larger service and a larger sphere. The humble retailer can burst the walls of his small store, just as Timothy Eaton did, if he gets the right idea and follows it. It is not a matter of brain or education so much as of purpose joined to energy and labor. The salesman or manager or bookkeeper or secretary can lift himself to a higher plane of service and rewards if he prepares himself diligently for larger work and pay. The small manufacturer, the company director, the broker—all can become enlarged in the nature of their enterprise and in the amount of their income—by resolutely setting themselves about the task of growing to be bigger-minded men.

Specialized information is the great idea. This is what the world pays handsomely for. And to acquire specialized information is really a simple matter, calling for the purposeful and faithful use of time. This chiefly.

One does not have to stop his ordinary work, or go to a university, or to any school. One can acquire the specialized information in the margin of time which is his own—in the after-hours of business. Which means: If a man will read the right kind of books or publications, and make himself a serious student at home, in his hours—the evening hours or the early morning hours—he can climb to heights of position and pay that will dazzle the inert comrades of his youth or day's work.

IF business—BUSINESS—is your chosen field of work, we counsel you to read each week THE FINANCIAL POST. It will stimulate you mentally. It will challenge you to further studious effort. It will give you glimpses into the world of endeavor occupied by the captains of industry and finance. With the guidance of the POST, and with its wealth of specialized information, you, a purposeful man, aiming to go higher in life and pay, will find yourself becoming enlarged in knowledge and ambition, and will be acquiring the bases and facts of knowledge which become the rungs of the ladder you climb by.

It is the first step which costs. But this cost is trivial—a single dollar. We offer you the POST for four months for a dollar. Surely it is worth a dollar to discover how right we are in our argument. If you have the will to go higher in position and pay, sign the coupon below.

THE MACLEAN PUBLISHING COMPANY, LIMITED,
.—143-153 University Avenue, Toronto.

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive all offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

In Canada's Biggest Industries

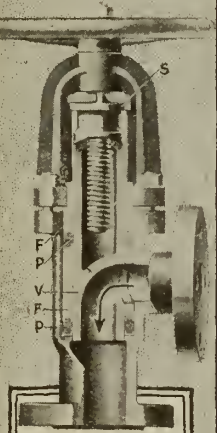
Where absolute certainty must be counted upon at all times, no chance can be taken with equipment.
In the big industries, especially, must every detail be efficient—the blow-off valve as well as the boilers, pumps and engines.

So, when the big Canadian corporations such as the following instal Yarway (formerly Simplex) "Seatless" Blow-Off Valves, their choice becomes an endorsement of the very highest character.

Canadian Explosives Co., Ltd., have 11.
Dominion Iron & Steel Co., Ltd., have 20.
Canadian Pacific Rly. Co. have 24.
Bathurst Lbr. Co. have 8.
Montreal L., H. & P. Co. have 24.
International Eng. Wks., Ltd., have 13.

And there are many others, With the Yarway (formerly Simplex) "Seatless" Blow-Off Valve there can be no sudden opening and closing to injure tubes; the operation is simple, certain and safe; the valve does not leak; it requires but little attention as there are no weak places such as seats or discs to cut and scar; even the packing lasts for years. You can verify each of these claims by testing the Yarway on one of your boilers for 60 days. Return it if not satisfactory.

Write to-day, stating size of line, and whether screwed or flanged, angle or straightway.



Operation: In closing valve shoulder "S" on plunger "V" engages the loose follower gland "F," compressing packing "P" above and below the port, making an absolutely tight valve.

A Timely Service --- and the Company behind it

The public wants better steam heating service—more comfort per ton of coal. This Company is in a most favorable position to meet this demand through its co-workers—the architects, heating and ventilating engineers, heating contractors and builders—to whom it offers practical co-operation that will increase their prestige as well as their volume of business.

Any man who uses, specifies or installs steam heating equipment will find it advantageous to learn more about Dunham Heating Service—the product of 15 years' knowledge of steam heating in all its phases.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction.* Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs.* Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

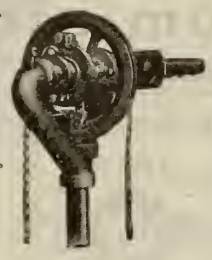
SAVE 4 to 8 PER CENT FUEL

COST MORE AND WORTH MORE

STANDARD OF THE WORLD

Where Shall We Look For Profits?



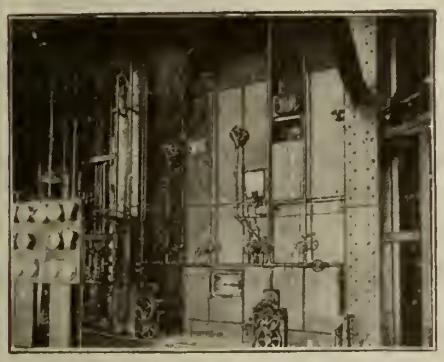
Taxes are high. Labor is high. Keen competitive conditions are being re-established. The trend of prices at which commodities can be sold is downward.

Yet business must be conducted at a profit!

How can this be accomplished? Only by increasing operating efficiencies.

In particular, the cost of producing power CAN and MUST be reduced. Equipment essential for this purpose is Diamond Soot Blowers.

In the average plant Diamond Soot Blowers will effect the following economies:



Diamond Soot Blowers at Plant of Buffalo General Electric Co.

1. Fuel; a saving of 4 to 8 per cent.
2. BOILER EFFICIENCY; an increase of 4 per cent.
3. LABOR; a saving of many hours per day.
4. LONGEVITY; an increase in the length of service of boiler tubes, through the prevention of corrosion.
5. STEAM; a saving of 25 to 75 per cent. of steam used for cleaning.

Such savings as these show up handsomely in your annual profits. If your plant is not equipped with Diamond Soot Blowers, ask for Bulletin No. 119.

Diamond Specialty Company

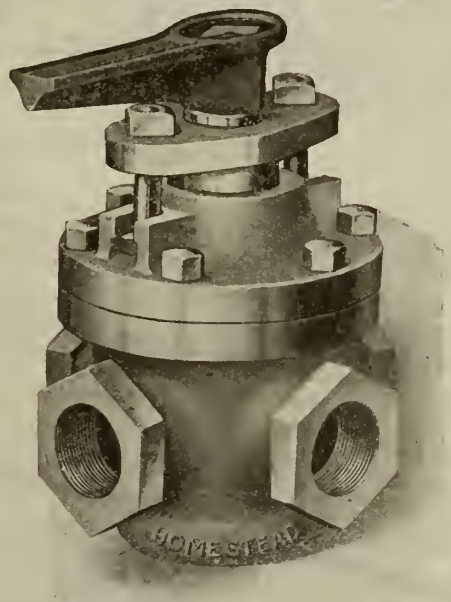
Windsor Ontario

MADE OF CALORIZED STEEL

HOMESTEAD
Quarter-Turn Valves

They Stay Tight

Because the seating surfaces are always exposed and subject to cutting and scoring it is practically impossible to keep globe or gate valves tight for any length of time when the service is severe.
Homestead Quarter Turn Valves are seatless. They stay tight.
Only one quarter turn of a convenient handle is required to open or close these high grade plug valves. Adopt them and you'll save time, trouble and expense.
Homestead Valves are made in straight-way, three-way and four-way patterns.



"HOMESTEAD FOUR-WAY VALVE"

Homestead Valve Mfg. Co.
HOMESTEAD, PA.

922 POWER Vol. 48, No. 23

Coal Saving by the Scientific Control of Steam Boiler Plants*

By D. Brownlie

THE author has been associated for about ten years with the investigation on scientific lines of the working of every description of steam-boiler plant, and in the present article it is proposed to give the average figures for 250 typical steam boiler plants, with the object of supplying accurate data as to the tremendous national economy that can be effected by tha adoption of acientific methoda in the boiler-house.

In the burning af coal for the generation of steam, the loss because of lack of scientific methoda is hardly realized and, apart from the national point of view, offers to the individual firm a means of most substantial economy in running expenses.

It is not possible to find out what is the exact amount of coal used for the production of steam for purposes other than power, there being, for example, no statistics available showing the number of steam boilers at work in Great Britain.

The author proposes therefore to assume, until further information can be obtained by a proper engineering census of the country, that the total amount of coal used for steam generation in the United Kingdom is between 75 and 100 million tons per annum, being 60 to 70 million tons for power production and 15 to 30 million tons for purposes other than power, corresponding to 40 per cent. to 53 per cent. of the total coal used, and is of the opinion that the 250 boilers to be dealt with in the present article are really representative of all the boiler plants of the country, and the results of such a very large number of exhaustive investigations carried on continuously during ... enable us to judge with ... rine" boiler, 2 "vertical" boilers, and 3 "patent" boilers difficult to classify. It would be most interesting to know the exact number of each type of steam boiler at work in the country, although there is no doubt that the chief type in use is the "Lancashire."

Amount of Fuel Used—The average shows 20.9 lb. of fuel burnt per square foot of grate area per hour, referring, of course, to the average amount burnt per hour per working day, and not to the amount for any particular hour. This figure is considerably below what is possible on a boiler plant run on modern lines, which would burn something like 25 lb. to 30 lb. per square foot grate area per hour with the average quality of fuel. The boiler plants of the country are working under very easy conditions in this respect, and much more fuel could be burnt per boiler. Figures for fuel consumption depend largely on the quality of the fuel. Thus a good quality washed coal of, say, 13,000 B.t.u. and 7 to 8 per cent. ash could easily be burned economically at the rate of 35 lb. per square foot per hour, whereas purely refuse coals would only give ... Coke of good quality can be burnt ... per square foot grate ... 15 pounds.

... to the efficient ... some other ... works.

Economizers—Out of the 250 plants, 155 were fitted with economizers, the other 95 plants having no means of utilizing the waste heat from the boiler flues.

Taking the 155 plants fitted with economizers, the average saving is 11.4 per cent. of the coal bill. The highest figure found was 19 per cent. on a cotton-mill plant. The ordinary figure obtained on a well-managed plant is 15 to 20 per cent. saving, depending on the conditions.

Estimation of CO_2—Out of the 250 plants, 225 ... not ... recei...

MAGNOLIA ANTIFRICTION METAL

FOR MAIN BEARINGS

BOOTH FISHERIES COMPANY
Packers of
Columbia River Salmon
Astoria, Ore.

Magnolia Metal Co. Oct. 15, 1918.

Gentlemen:—

I first used MAGNOLIA METAL in 1889 on the Crank-Pin of a high-speed engine in a saw mill. This bearing had given considerable trouble before we babbitted it with MAGNOLIA, and to my knowledge this bearing was still in good shape for several years after.

Twelve years ago I ran the Main Bearings on large ice machine here and to-day these same bearings are doing duty just as smoothly as the day they were put in.

I recommend MAGNOLIA METAL whenever the opportunity presents.

Yours very truly,
G. A. SCHULTZ,
Chief Engineer.

Imperfect combustion is the cause of almost all fuel waste. It is responsible for the formation of waste flue gases.

Sometimes an obstruction in the stack or chimney, or in the construction of the chimney itself, aggravates the trouble. But the real cause—the thing that makes imperfect combustion—can nearly always be traced to the use of poorly designed grates.

Cyclone Grates

Stop Fuel Waste

by using grates designed to do that—Cyclone Shaking and Dumping Grates. The 60% Air Space and 90% Underdraught provided by these grates put a stop to imperfect combustion, to clinker formation, to fuel waste. Write for our 30-day Trial Offer.

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914 With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

POWER HOUSE BUYERS' DIRECTORY

If what you want is not listed here write us, and we will tell you where to get it. Let us suggest that you consult also the advertisers' index facing the inside back cover, after having secured advertisers' names from this directory. The information you desire may be found in the advertising pages This department is maintained for the benefit and convenience of our readers. The insertion of our advertisers names under proper headings is gladly undertaken, but does not become part of an advertising contract.

AIR COCKS
Lunkenheimer Co., Cincinnati, O.
Penberthy Injector Co., Windsor, Ont.

AIR VALVES
Mueller Mfg. Co., H., Sarnia, Ont.

AMMETERS
Canadian Fairbanks-Morse Co., Ltd., Montreal.
Can. H. W. Johns-Manville Co., Toronto, Ont.

AMMONIA VALVES AND FITTINGS
Canadian Fairbanks-Morse Co., Ltd. Montreal.

W. D. Anderson's Engineering Efficiency Service

Manufacturers often spend thousands of dollars on additional buildings and equipment in order to get greater output and profits long before their product reaches 80 per cent., or their profits 50 per cent. of what may be easily secured from the facilities they already have.

Are you satisfied with your output? We can and will increase your production.

Ring up Anderson's Efficiency Service
PHONE 221 ADELAIDE
380 Queen West Toronto, Canada

ECONOMY renewable FUSES

Protect millions of electrical circuits for thousands of users throughout North America.

The Economy is a *pioneer* renewable fuse. It is widely imitated, but not duplicated. It is accurately rated—that means safety. Can be oftenest renewed at least cost per renewal—that means economy.

An inexpensive "Drop Out" Renewal Link restores a blown Economy Fuse to its original efficiency.

Wary buyers order by brand.

Write for Catalogue 24

Economy Fuse & Mfg. Co. of Canada, Ltd.
Unity Building - Montreal
Manufacturers in Canada of S. & C. High Potential Fuses—to 150,000 volts.

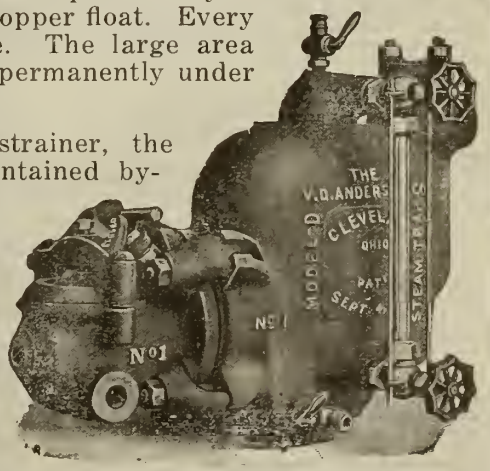
The ANDERSON
Model "D" Steam Trap

Stays Tight

Your condensation trouble may be an old-standing problem that you have never been able to solve. Conditions in your plant may be unusual—extremely severe. Nevertheless, the Anderson Model "D" Steam Trap will stay tight from the day you put it in.

It will save you expense and trouble because it will work perfectly under high or low pressure. It is operated by a counterbalanced Lake Superior Copper float. Every part is machined to solid gauge. The large area valve will not wire draw and is permanently under deep water seal.

Moreover, the self-contained strainer, the outside gauge glass, the self-contained by-pass and complete accessibility to all parts are other Anderson features that make for high efficiency and low-cost service.



Write for Descriptive Booklet.

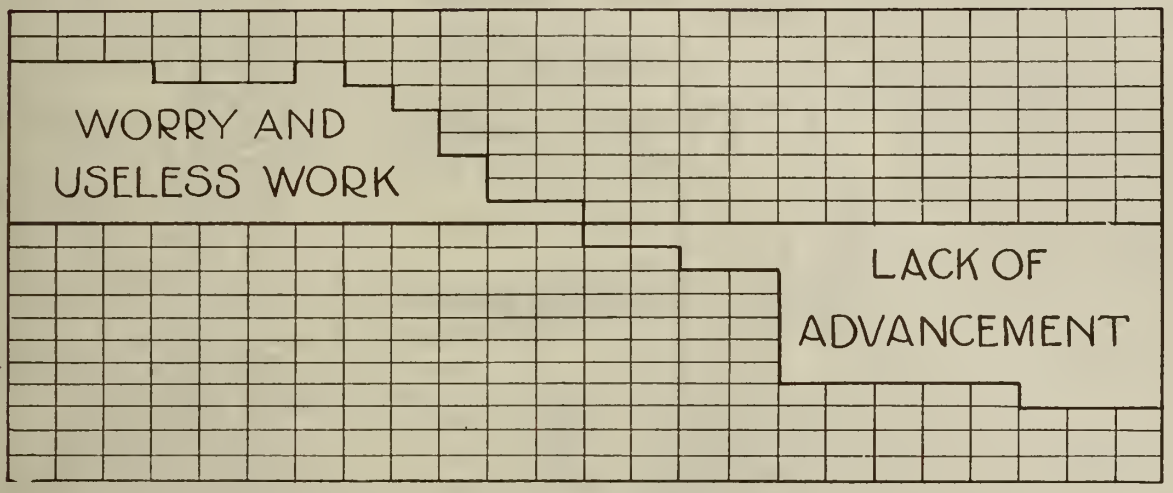
Let the C.A.S.E. Smooth Out Your Load Curve



Remove The Peaks of Worry And Unproductive Labor And Build Up The Valleys By Working For Your Advancement

A man who is thoroughly grounded in the practice of his profession, who is free from personal worry and trouble, overcomes the many difficulties besetting the path of the operating engineer with little labor and in a manner ensuring his advancement.

The successful man owes his success to a wise appreciation of the advantages and mutual help offered by association with those in the same field of endeavor. To join an association having for its objectives the welfare of the engineer in things mental and material, his advancement in knowledge and skill, his protection by provision for sickness and distress is to take advantage of an opportunity indispensable to all who hope to better themselves.

If you are interested in such an organization and live where less than fifteen engineers are located, send for a copy of our constitution and application blanks for admission to nearest branch lodge. If there are more than fifteen engineers in your community, get together and send for particulars regarding formation of a branch lodge.

J. H. HALE, General Secretary,

Tycos

TEMPERATURE INSTRUMENTS

Indicating, Recording, Controlling

Stand first in temperature problems, having won their superior position by painstaking and exact service in innumerable industrial applications. They do their work well, perform every duty demanded of them in temperature problems efficiently. The large number of satisfied users is ample indication of the confidence modern industry has in *Tycos* products.

Tycos is the answer to your Temperature Problems.

Taylor Instrument Companies

Rochester, N.Y.

There's a Tycos Thermometer for Every Purpose.

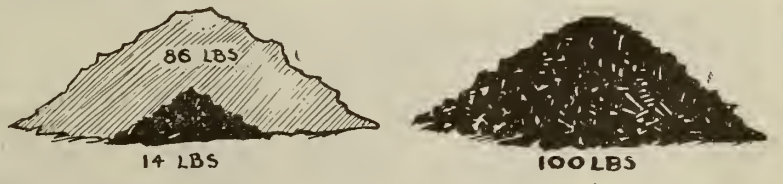
Coal used With and Without



the **COLE Return Trap**

The above two piles of coal tell the whole story. The all-black pile shows the relative amount of coal required to steam a boiler using a direct steam pump; the black part of the other pile, the relative amount required for the same work with a Cole Return Trap. This Trap will save you 86% of the coal used without it.

Geo. W. Cole, Limited 2002-4 Dundas St. W., Toronto, Ont.

Condensation BACK TO THE BOILER HOT

Use your condensation. Take it out of your steam lines and return it to your boilers as pure HOT feed water. This is made possible by using the

Morehead "Back to Boiler" System

Saves fuel and increases efficiency of steam-heated equipment. Requires practically no attention and is always reliable.

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

POWER HOUSE

A monthly newspaper devoted to the Generation, Transmission and Application of Steam, Gas, Electric, Air and Water Power; and to the operation of Refrigerating Machinery.

Published by The MacLean Publishing Company, Limited, 143-153 University Ave., Toronto

MONTREAL: Southam Bldg. LONDON, ENG.: 88 Fleet St., E.C. WINNIPEG: 1207 Union Trust Bldg

Vol XIII.—No. 4. Publication Office, Toronto—April 5, 1919 Published Semi-Monthly $1.00 per Year

Installing good valves at the start saves repair and replacement charges as well as labor cost of reinstallations later.

JENKINS BROS.' TYPE "K" Brass Gate Valves are representative of the highest type of Gate Valves made. They are improved in design and constructed from carefully selected materials by first-class workmen, and are thoroughly tested under working conditions by both steam and hydraulic pressure previous to shipment, thus we are able to give a genuine guarantee of good service with every Type "K" Valve.

You will know a JENKINS BROS.' TYPE "K" GATE VALVE by the Diamond Trade Mark which is cast on the body of all Genuine—Look for it. Stocks at all Dealers.

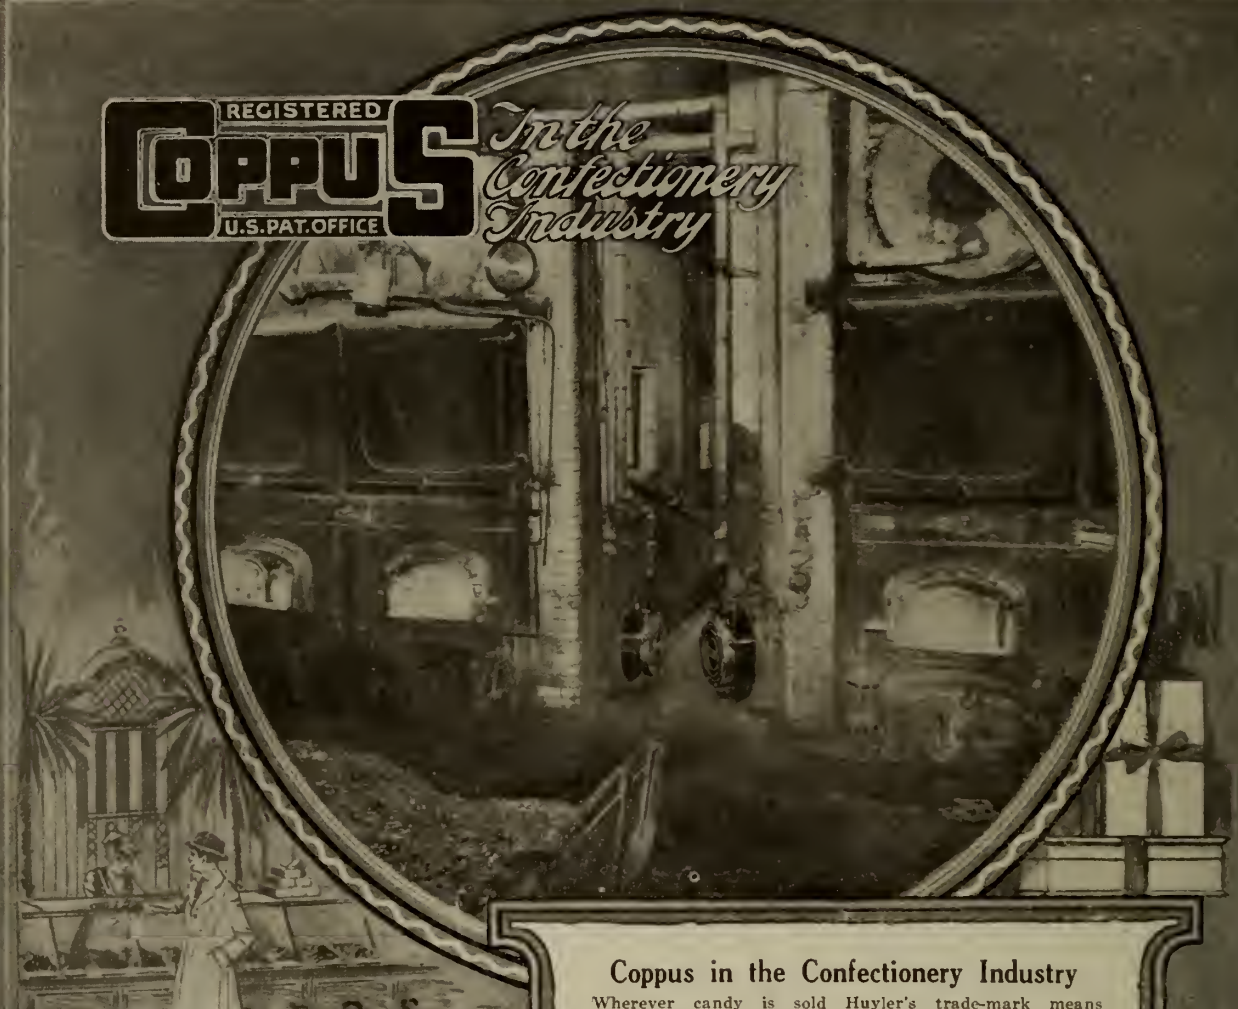
In the Confectionery Industry



Coppus in the Confectionery Industry

Wherever candy is sold Huyler's trade-mark means quality supreme. Wherever candy is **made**—there is an opportunity for COPPUS Turbo Blowers to save money in power plant operation.

These two 18" Blowers have been economizing time, fuel, and labor in the boiler room of the Huyler's Chocolate Company, 136 East 18th Street, New York City, since July, 1917. They burn inexpensive fuel—keep up full steam pressure—and meet peak loads without extra exertion by the engineer, **quickly, easily, cheaply.**

They can do this better than any other type of blower because of their

Standardized Construction
Rugged Reliability
Economy of Operation

What COPPUS Turbo Blowers are doing in other plants they can do in yours. If you will ask us we will be glad to send you complete information showing just how COPPUS Turbo Blowers can help you secure more power from your present equipment and greatly increase the efficiency of your power plant. Ask for catalog.

COPPUS TURBO BLOWER

BOILERS

Waterous Horizontal Return Tubular Boilers are unexcelled for use in municipal power and pumping plants and for the production of steam for general heating purposes.

They are economical of fuel—carry a big reserve steam pressure for use in emergencies—can be used with hard and dirty water and are readily cleaned and easily taken care of. They cost little new,—their upkeep and maintenance expense is negligible.

We build all sizes from 40" x 10' to 72" x 18', and supply them complete for any installation, whether for power production or for heating systems.

Our numerous installations in Provincial and Municipal institutions throughout Canada vouch for the quality of our product.

BRANTFORD, ONTARIO, CANADA

Entire Plants and Equipment For Sale

O'BRIEN MUNITIONS, Limited and ENERGITE EXPLOSIVES

RENFREW, ONTARIO

THIS is probably the most attractive offering ever placed before Canadian manufacturers, and one that is worthy of your most careful consideration.

The Geographical location of the Town of Renfrew and uniformly permanent construction of the plants themselves, which are situated just a few minutes' walk beyond the Town limits, makes it an opportunity that comes but once in a lifetime.

Plenty of cheap electric power, town water on all parts of the property, excellent labor conditions and completely equipped Industrial Railway connecting all parts of the Plants. Canadian Pacific and Grand Trunk Railway sidings bring shipping and receiving facilities up to a maximum of efficiency. Free from Town taxation.

To those interested we will be glad to forward ground and building blue prints, inventory of Plant Equipment, including machinery of all descriptions, together with complete office and housing furniture, etc., all in first-class condition.

Tenders will be received for any part or all of these plants' equipment, as well as the land and buildings thereon erected. We are not setting a price on this "Manufacturing Opportunity." Write for full particulars, investigate and—

Make an Offer.

Highest or any tender not necessarily accepted.

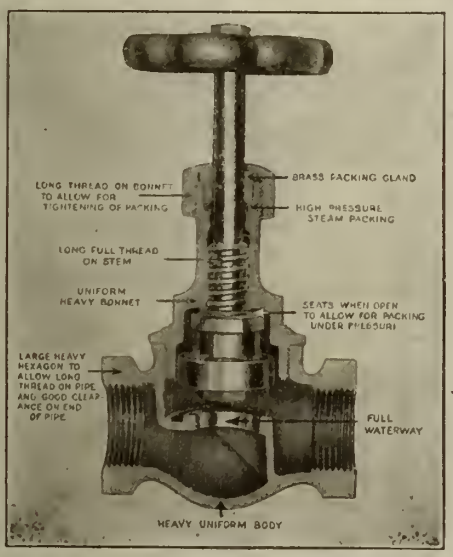
Waste of Time and Money



LONG THREAD ON BONNET TO ALLOW FOR TIGHTENING OF PACKING
BRASS PACKING GLAND
HIGH PRESSURE STEAM PACKING
LONG FULL THREAD ON STEM
UNIFORM HEAVY BONNET
SEATS WHEN OPEN TO ALLOW FOR PACKING UNDER PRESSURE
LARGE HEAVY HEXAGON TO ALLOW LONG THREAD ON PIPE AND GOOD CLEARANCE ON END OF PIPE
FULL WATERWAY
HEAVY UNIFORM BODY

WHEN overhauling your equipment, don't patch up the worn parts, it wastes time, labor and money—to say nothing of reduced plant efficiency, and lower turnout.

Everything wears out in time, even if it does take years to happen, and renewals *must* be made.

About your valves—if those you have installed do not do their job, don't tinker with them—it will cost you more money than they are worth.

Get "EMCO" Valves. They have nine points of superiority. The accompanying cut will show you this.

EMCO Valves are guaranteed efficient, strong and durable. The design is approved and registered in the Provinces of the Dominion by Inspectors of Steam Boilers for a working pressure of 175 pounds. They are made of the best Bronze Metal. Each valve is subjected to a thorough hydraulic test before leaving our factory.

Look for the word "EMCO" on each valve.

Write for our catalogues. They contain valuable information you no doubt require.

Registered in the following Provinces as follows:—

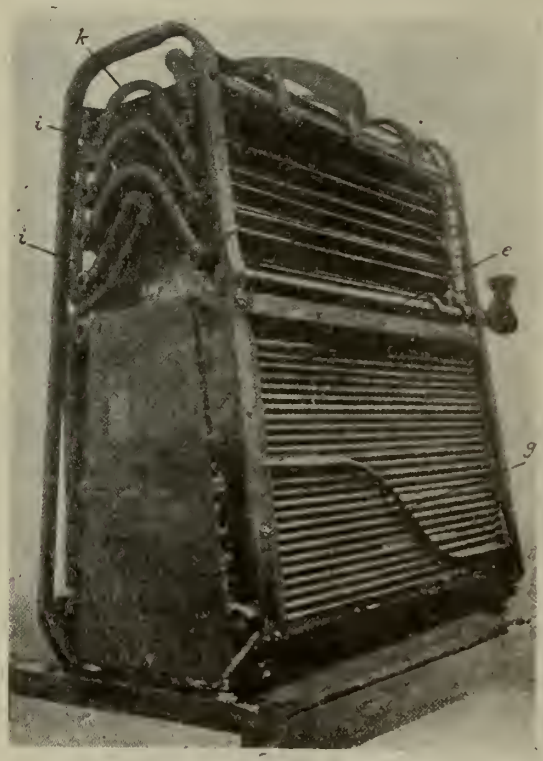
TALBOT

Contra-Flow Steam Boilers

(Equipped with Crude Oil Burners)



Head of Boiler Casing Removed

Talbot Oil-Fired Boilers require about one-seventh the space of the ordinary boiler. No brickwork is necessary and the cost of operation is cheaper than any known power producer.

The "Talbot" is a boiler of the contra-flow type, water entering near the stack and leaving in the form of steam near the furnace.

The circulation is through water tubes and is forced at a high velocity by means of a pump, doing away with a water drum. By preventing gravity circulation the steam is drawn directly from the lower tubes, eliminating the steam drum. The boiler is internally fired, and hence self-contained. Feed water and fuel burners are automatically controlled to adjust the boiler to widely varying demands for steam.

Tubes easily replaced under high steam pressure.

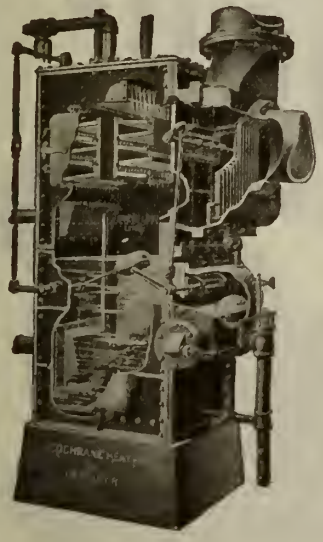
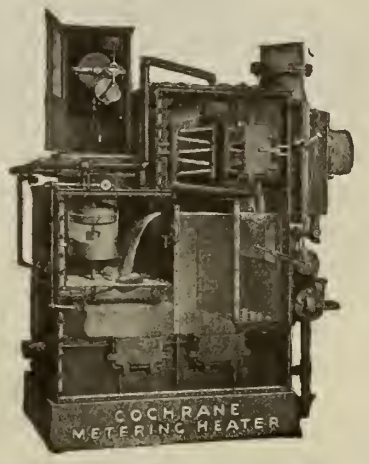
COCHRANE
COAL SAVERS

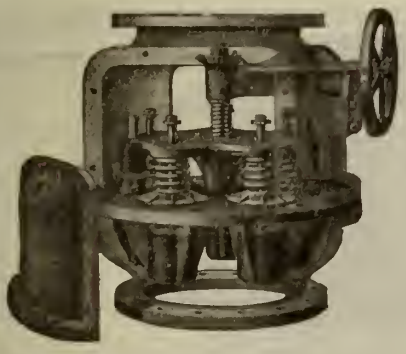


The Cochrane Open Feed Water Heater saves coal by utilizing exhaust steam to heat the feed water; 1% saving for each 11° F. rise.

The Sorge-Cochrane Hot Process Water Softener saves coal by heating the boiler feed water and by protecting the boilers against scale and corrosion.



The Cochrane Metering Heater saves coal by heating the feed water and helps save coal by telling whether or not the plant is being operated economically.



The Cochrane Multiport Back Pressure Valve saves coal by preventing leakage of exhaust steam and by making it easy to adjust the back pressure whenever desired. The Cochrane Oil Separator saves coal by rendering the exhaust steam useful for heating, drying and other purposes.

The Cochrane Oil Separator saves coal by rendering the exhaust steam useful for heating, drying and other purposes.

Canada is Saving Many Thousand Tons
of Coal Per Year by Using Cochrane Heaters

Here are the figures:

The **horsepower** of Cochrane Heaters in use is about 10,000,000 boiler horsepower.

The corresponding amount of **coal burned** is 35,000,000 lb. per hour.

Considering an average of 10 hours' operation per day, 300 days per year (many heaters run 24 hours per day, 365 days per year), this amounts to 105,000,000,000 lb. of coal per year, or 50,000,000 tons, worth at $5.00 per ton, $250,000,000.

The saving due to the use of **Cochrane Heaters** is 1% to each 11° F. rise in temperature. On the average, the water is raised from 100° F. to 210° F. using steam at atmospheric pressure, 10% or a saving of 10%. Cochrane Heaters are thus **saving about $25,000,000** per year, which is vastly more than the heaters cost.

In addition, Cochrane Oil Separators are saving millions of tons of coal by **purifying exhaust steam** so that it can take the place of live steam in heating and drying coils, low-pressure turbines and industrial processes.

Sorge-Cochrane Hot Process Water Softeners are saving millions by **keeping scale and corrosive substances out of boilers** and thus saving expense and labor in cleaning boilers, and for new tubes and other boiler repairs.

Cochrane Metering Heaters are also telling hundreds of **steam-plant owners**, managers and operators how much they are **gaining in economy** by using different coals, different methods of firing, different methods of controlling the draft, stopping up air leaks in boiler settings, cleaning soot and scale from heating surface, etc. The total gains realized in this manner often amount to 25% or more.

Our engineering department has given hard study to fuel economy for over 25 years. It will be glad to aid you with suggestions if you will describe your present boiler feed water heating, softening, or metering arrangements, the amount of exhaust steam you have available and what you are using it for.

The ANDERSON
Steam Trap

From the day you put it in, this Anderson Model "D" Steam Trap will stay tight. Operated by a counter-balanced Lake Superior Copper float, it will work perfectly under high or low pressure in any boiler-room. Its every part is machined to solid gauge. Its large area valve, permanently under deep water seal, will not wire draw.

We venture to say you never saw a trap made with the painstaking care that makes this Anderson Trap permanently tight under conditions most trying. It has a self-contained strainer, an outside gauge glass, a self-contained by-pass. And its construction affords complete accessibility to all parts.

This Anderson Trap will save you expense and trouble and time. Install it in your boiler room. Booklet on request.

THE V. D. ANDERSON COMPANY
1935 West 96th Street, CLEVELAND, OHIO

Stays Tight

No Clinker formation
No Coal lost in the ash pit
No Waste with--

You might call these the perfect-combustion-making grates because their 60 per cent. air space and 90 per cent. underdraught extract from fuel the last atom of energy. Burning any grade of coal, even screenings, these Grates prevent the formation of clinkers, for their use insures perfect combustion, no matter how good or how poor the fuel used. In every power plant in which these Cyclone Improved Shaking and Dumping Grates are used, steam costs less for the reason that less fuel is used. Your engineer can install Cyclone Grates without delay or trouble. You can have them on 30 days' trial.

One Man in a RILEY STOKER PLANT Can Often Care For 5,000 to 10,000 Horse-power of Boilers.

Live Grate Surface

One feature alone of the RILEY STOKER — *its moving grates* — is worth the hand work of a dozen skilled operators.

Even the most skilled would find it impossible to keep the fuel-bed free from holes and clinkers without dropping the efficiency by opening the fire-door.

The RILEY STOKER moving grates keep the fire-door shut—the fuel-bed open and porous—and discharge the ash as fast as it is formed.

The *moving grates* of the RILEY STOKER not only intensify combustion but enable the stoker to burn the poorest coals obtainable economically and at high capacity.

GARLOCK

NINE HUNDRED SHEET

Is unsurpassed for superheated steam joints.

It is equally well adapted to air, acids, ammonia,

Or any severe condition where sheet packing is required.

It is made of the highest quality of long fibre asbestos,

And is built up into sheet form under tremendous pressure,

Thus securing great toughness, flexibility and tensile strength.

It is not affected by extremely high pressures and temperatures,

And does not require following up after gaskets have been applied.

Joints can be opened as often as desired without injury to gaskets.

This sheet is furnished in all thicknesses from 1/64 inch to 1/4 inch.

Gaskets of all shapes and sizes can be cut by us from Nine Hundred Sheet.

Handle it Mechanically

With The JEFFREY Improved Carrier

Mr. Power Plant Engineer, your reputation is in the hands of the public, and no one has more at stake, for you must keep the wheels of industry moving and assure the many comforts of the home by supplying electric power, steam, light, heat and water.

Your Engineers and Generators, Boilers and Stoker Equipment may be the best that money can buy, but unless you have an adequate and efficient system for bringing the coal from the cars to the stokers, you cannot insure the continuous service demanded.

The Jeffrey Improved Carrier

represents the supreme development of the Pivoted Bucket Carrier for the handling of coal and ashes in the power plant. It has proved in many installations over the country, its Reliability of Action and Qualities for Long and Satisfactory service.

In presenting our New Catalog No. 210-A on the Jeffrey Carrier we believe we are rendering a service to the engineer and to the public. Write for a copy of this book.

After Five Years' Service at Zero

"It is with pleasure that we speak most favorably regarding the way Nonpareil Corkboard has stood up in our ice cream room," wrote Mr. N. B. Kuhlman, President, Mono Service Cream Company, Knoxville, Tenn., on October 28, 1918. "The corkboard was put into the hardening room something like five years ago. We have never had any cause for complaint, and our hardening room stands at a temperature of zero to ten below. If we ever enlarge or build additional hardening rooms, we will certainly insulate same with your Nonpareil Corkboard."

That seems to be the general opinion among ice cream men regarding

Nonpareil Corkboard Insulation

For Hardening and Cold Storage Rooms

Of course, there is a good reason for it. Nonpareil Cork combines all the essentials of a satisfactory cold storage insulation. It is a fine non-conductor of heat; it does not take up moisture; it keeps free from mold or rot; it is easy to install in all kinds of buildings; and lasts almost indefinitely when properly erected. That's why the Mono Service Cream Company and many others all over the country specify Nonpareil Corkboard when they build new plants or make repairs and additions.

You, too, will swear by Nonpareil Cork if you once try it. Now is a good time to investigate. Literature and samples will be sent on request.

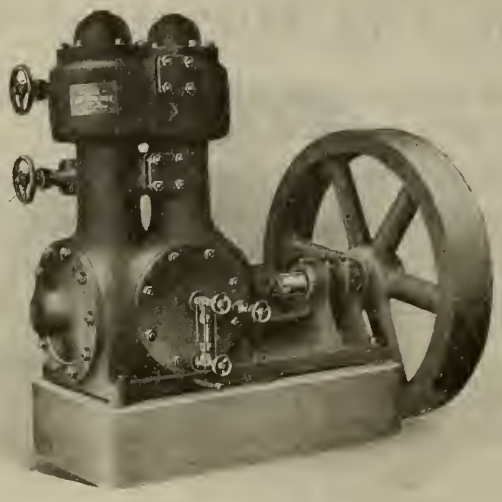
Quality Products Leave No Regrets



York Ice-making and Refrigerating Machinery is not made to fit the price. We have a standard of quality and service which has been maintained ever since the York Organization was started.

It is betraying no secret to say that many owners of ice-making and refrigerating plants have expressed to us, by word and letter, their keen regret at having turned down a York contract because the price seemed too high.

Price is a poor gage to use in buying such important equipment as Ice-Making and Refrigerating Machinery. Confidence is a better one. You know from your own experience that business born of confidence begets new business.

No customer can truthfully say that the York Organization ever tried to take advantage of him. It is on this basis that we have been selling our products, and it is for this reason that we have been successful.

An inquiry from you will be appreciated. You are not obligated to buy York equipment until you are satisfied as to its quality and our good intentions.

Hays CO_2 and Draft Recorder

Tells the Story of Boiler Efficiency

The exact reason why 30 to 50 per cent. more fuel is consumed in your plant than should be, is shown by the Hays CO_2 and Draft Recorder. With these appliances installed, your firemen can fire intelligently; they will work with accurate facts before them—instead of groping in the dark. For Hays CO_2 and Draft Recorder permanently record the story of efficient combustion

and Point Out Errors in *Firing, Draft, Boiler Settings, Etc.*

YOU

need this Hays CO_2 and Draft Recorder to fire your Boilers intelligently

Hundreds of plants are using these Hays Appliances and saving 30 to 50 per cent. of their fuel expense as a result.

The Hays Recorder is automatic, self adjusting, infallible. It does not depend on hand adjustment and mechanical action for accurate operation. Indications are controlled by rising and falling columns of mercury, water and caustic potash.

We invite you to investigate, believing the facts will convince you that these Hays Appliances would quickly earn their cost in your plant.

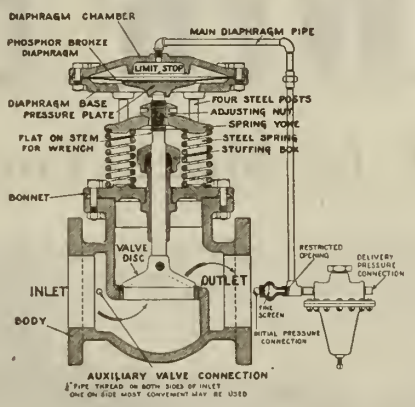
Hays Differential Draft Gauge

MUELLER Reducing and Regulating Valve

SINGLE SEAT; AUXILIARY OPERATED



E5030 for Water, Gas and Air
E5130 for Steam
(Flanged or Screwed)

Very Popular with Shipbuilders

USES

This valve is for use on exacting installations. It will make any desired reduction and will maintain a constant delivery pressure regardless of fluctuations of the initial pressure.

CONSTRUCTION OF STOCK REGULATORS

All valves have iron bodies, bronze stem and stuffing box, phosphor bronze diaphragms, seats of composition suitable for the required service; iron diaphragm chamber and steel springs. The main valve is controlled entirely by the small auxiliary valve. This auxiliary valve closes and opens the main valve by admitting initial pressure to, and releasing it from, the diaphragm chamber of the main valve according to the demand of the delivery side. Regulators of this description are suited for pressures up to 150 pounds, and will be furnished at above prices. When regulators are required for pressures in excess of 150 pounds we will furnish suitable material. Prices upon application.

STRAINER

In all cases it is advisable to use a strainer to prevent obstruction from grit, scale, cuttings, etc. Blow out pipes thoroughly before installing valve.

INFORMATION IN ORDERING

In ordering give highest and lowest initial pressure and required low or delivery pressure, approximate quantity or volume to be used per minute, size of high pressure pipe and low pressure pipe.

In ordering flanged end valves give diameter of flanges and bolt circles and the number and size of bolts.

INSTALLATION

Note—Any proper working regulator acts as a check valve. Where the building up of the pressure is to be avoided use our diaphragm operated relief valve E5060.

We will not be responsible for improper selection of valves.
Consult us regarding the best type for your service.

The Coquitlam Buntzen Hydro-Electric Plant

One of the Most Interesting Hydro-Electric Developments in British Columbia Supplies Power to Vancouver and Adjoining Municipalities

By F. C. PERKINS

THE water powers of British Columbia are all of great importance, but the Coquitlam Buntzen Hydro-Electric development is of special interest, as shown in the accompanying illustrations and drawings, which give the details of construction, which are worthy of careful study. Coquitlam Lake and Lake Buntzen may be noted in the photographs, as well as the Coquitlam dam, pipe lines and the electrical equipment.

The power house No. 1, as well as power house No. 2, at Lake Buntzen are thoroughly up-to-date, and the transformer electrical equipment and high tension switch rooms of the No. 2 station of the Coquitlam Buntzen Hydro-Electric British Columbia development are modern in every respect.

One of the British Columbia Hydro-Electric plants, which supplies power to the City of Vancouver and the adjoining municipalities, was first placed in operation in 1905. This plant was originally designed for 12,000 horse power, and was at that time considered of sufficient magnitude to meet the needs of the district for many, many years. Owing to the enormous expansion of Vancouver and the surrounding territory, the Lake Buntzen plant has grown to 85,000 horse power, while the City of Victoria is now supplied from Jordan River, forty miles east of the city, and together with the Goldstream plant has power available up to 38,000 horse power installed to meet the industrial needs of the community.

It is estimated that within reasonable distance of the cities of Vancouver and Victoria, without going beyond the present-day limits of long distance electrical transmission, 750,000 horse power can be economically developed, a possibility that will place these cities among the most favored for the expansion of many existing and future industries. Among other notable powers of the provinces is that of the Powell River, where 24,000 h.p. is utilized in the manufacture of pulp and newspaper. At Ocean Falls, 11,000 h.p. is utilized for the same purpose.

POWER HOUSE, SHOWING ATTRACTIVE EXTERIOR

The writer is indebted to J. T. Johnston, of the Dominion Water Power Branch, for the accompanying photographs, and to R. G. Conway for the engineering data of the water powers of the Province of British Columbia. The Coquitlam Buntzen Hydro-Electric power scheme for the supply of electrical energy to the City of Vancouver, and the municipalities of the lower mainland of British Columbia is owned and operated by the Vancouver Power Company. This company was incorporated under the provisions of the "Water Clauses Consolidation Act" of the Statutes of British Columbia, and is a subsidiary company of the British Columbia Electric Railway Company, Ltd., which controls the electric railway, light and power systems in the cities of Vancouver, New Westminster, Victoria, and the surrounding districts.

The original Coquitlam Buntzen scheme comprised the raising of the surface of Coquitlam Lake by means of a small rock-filled crib dam with crest 443 feet above sea level, and delivering the water so stored through a tunnel 2¼ miles long to Lake Buntzen, a small lake due west of Coquitlam Lake, and thence through steel pipes to a power house on the shore of Burrard Inlet, an arm of the sea. By the construction of a concrete dam at the north end of Lake Buntzen, an ideal forebay reservoir was obtained. When the original tunnel was designed, it was thought that ample provision had been made for any increased demand for water, which might occur on account of extensions to plant No. 1, Lake Buntzen, but the rapid development and growth of the district around Vancouver soon made it evident that the demand for power would, in a very short time, exceed the maximum capacity of the tunnel. After careful investigation it was decided that the existing development could be considerably enlarged so

COQUITLAM LAKE

as to utilize almost the entire run-off of the Coquitlam watershed. The enlargement of the Coquitlam Buntzen tunnel and the construction of a dam to increase the storage capacity of Coquitlam Lake was therefore decided upon; extensions were also carried out at the power house. By the time the enlargement of the tunnel had been completed, the rate of growth of the company's load was such that the construction of an entirely new plant at Lake Buntzen was decided upon.

It is of interest to note that Coquitlam Lake is the main storage reservoir of the scheme in the Province of British Columbia. The lake is about seven miles in length, with an average width of about one third of a mile. Its average summer level, prior to the building of the small crib dam at its outlet, was about 432 feet above sea level, and its ordinary area about 3,190 acres. The area of the watershed is approximately 105 square miles, and the mountains rise precipitously on either side to a height varying from 3,000 to 6,000 feet. The precipitation over the watershed for the last eleven years has averaged 153 inches. The winter snows over the watershed are heavy and remain on the higher peaks until late in the summer.

The original dam at Coquitlam Lake was built across the Coquitlam River a little below the outlet of the lake. It is a rock-filled crib structure of the overflow type, 170 feet in length, with the crest 443 feet above sea level and about 11 feet above the original level of the lake. It is 113 feet in length along the crest, and 9 feet of free board is provided. The new Coquitlam dam is of special interest. The precipitation and run-off records of Coquitlam Lake showed that in order to utilize the entire run-off from the watershed, a dam to raise the level of the lake another 60 feet was required. The site of the new dam at Coquitlam Lake is a little below the old crib dam, now buried in the upper toe of the new one. A dam of the hydraulic fill type with heavy rock toes was decided upon owing to the impracticability of obtaining a satisfactory foundation for a necessary dam, as bedrock was only revealed on the eastern portion of the site. The new dam is built upon a natural barrier formed at the outlet of the lake by a receding glacier, and is formed of fine blue and gray glacial boulder clays together with inter-stratified layers of cemented gravel and boulders.

The new dam was built with its crest at El. 518 and with spillway at El. 503. The maximum height of the dam above the lowest point of foundation on the centre line is 100 ft., the extreme width at the base is 655 feet, and the length along the crest, including the spillway, is 1,200 feet. The slope of the upstream face is 1 in 5, and of the downstream face, 1 in 2 to 1 in 4. The width of the spillway is 250 feet, with 15 feet of free board, which provides spillway capacity considerably in excess of any recorded flood. The construction of the new dam provides storage amounting to 180,500 acre feet available for power purposes. The total quantity of material in the dam amounts to 544,710 cubic yards. Of this quantity, 116,360 cubic yards consists of rock placed in the toes by hand and by cableways; the remainder of the material in the dam is sluiced material.

During the construction of the dam the outflow from the lake was carried around the dam site in a tunnel driven under the spillway. This tunnel has an area of 412 square feet and is 490 feet in length; it was designed to carry 12,000 cubic feet per second. For controlling the flow of water through this tunnel, permanent gates are placed in a concrete tower at its upper end. As the City of New Westminster has drawn its water supply from Coquitlam Lake for two decades, and as the raising of the lake level rendered the original intake works useless, an entirely new intake for the New Westminster water works had to be provided. The new intake structure is a substantial concrete tower founded on bedrock on the east side of the lake, about 1,000 feet north of the dam. The tower is circular in plan, with an inside diameter of 18 feet. In the walls of the tower four intake openings are provided, which are protected by screens and controlled by means of gates placed within the tower. A secondary intake is placed within the tower, so designed that water may be drawn off at any desired elevation. From the intake tower the water enters a tunnel about 2,000 feet in length, which passes under the spillway and also under the sluice tunnel. The lower end of the tunnel is connected by means of a pipe line, with a distributing chamber, from which the water supply mains for New Westminster emerge. For the protection of the New Westminster water supply, extensive clearing operations were carried out along the shores of the lake.

Regarding the Coquitlam-Buntzen tunnel, it is said that the total length of the tunnel, which conveys water from Coquitlam Lake to Lake Buntzen, is 12,650 feet. This work was begun in 1902 and completed in 1903. A square section about 9 feet by 9 feet, with rounded corners, was adopted, and it was designed to carry 500 cubic feet per second. The enlargement of this tunnel formed part of the program in connection with the extension of the Lake Buntzen plant. The section of the tunnel was increased to 192 square feet, which is sufficient for the ultimate development of the Coquitlam Buntzen scheme. The intake of the Coquitlam Buntzen tunnel was rebuilt when the new dam was constructed; it consists of a heavy masonry retaining wall founded on bedrock and built against the steep hill above the tunnel entrance. This entrance is protected by a trash rack 41 feet wide and 35 feet high, supported by heavy steel cables and counterbalanced so that it can readily be raised and cleaned. Two independent sets of head gates are provided for controlling the flow of water through the tunnel. One of these gates is of the Coffin type, 9 feet in diameter; the second set consists of two Stoney sluice gates, placed side by side. The operating gear for both ends of gates is placed in chambers cut in the face of the mountain well above high water level; the gates are arranged for operation either by gasoline engine or by hand.

In reference to the Lake Buntzen storage reservoir it may be stated that Lake Buntzen lies immediately to the west of Coquitlam Lake, from which it is separated by a range of mountains which reach an elevation of 4,000 feet. The precipitation at Lake Buntzen during the last eleven years is shown in the accompanying table. The average rainfall during this period was 112.53 inches.

The area of Lake Buntzen is about 500 acres and the drainage area about 7 square miles. By the construction of a concrete dam 54 feet in height and 361 feet long on the crest, an excellent forebay was provided. The elevation of the crest of Lake Buntzen dam is 400 feet above sea level. Ten outlets, 54 inches in diameter, with the necessary trash racks and hand-operated head gates, were provided for the connection of pipe

lines which convey water to power house No. 1, and two openings 24 inches in diameter were provided for the exciter pipe lines. It may be of interest to consider the hydro-electric equipment of the original power house known as Lake Buntzen power house No. 1, which is situated on the east shore of Burrard Inlet, about 16 miles from the City of Vancouver. The power house is built of hewn granite, the main floor being 5 feet above high water. The original installation had been added to from time to time, and the present equipment includes 4-1500 k.w. Westinghouse generators driven by Pelton water wheels, and a 5,000 k.w. Canadian General Electric driven by Pelton water wheels, and a 5,000 k.w. Kerr generator driven by Doble water wheels, and a 5,000 k.w. Canadian General Electric generator driven by Doble water wheels.

All of the above units are of the horizontal type, the water wheels and generator being in all cases mounted on the same shaft. In addition to the above equipment, four exciter units are provided. All of the generators are of the three phase, 60 cycle type, generating current at 2,200 volts. For regulation purposes, Tirrill regulators are provided. The generating equipment is installed on the main floor of the power house, 5 feet above high water level. The operating bench board and switch board are placed on the gallery along the back wall of the generating room. Behind the switch board the generator switches are situated, and on the floor above these are placed the low tension transformer switches.

The transformers and high tension switching equipment are housed in a separate building behind the power house The transformer equipment consists of three banks of three k.v.a. single phase, oil insulated, water cooled transformers, which step up the voltage from 2,200 to 36,000. This voltage will be increased to 60,000 at an early date. Electrolytic lightning arresters are placed in concrete shelters on the roof of the building. The high tension switches are of the K. 15 type and placed in a separate room behind the transformer compartments. All of the equipment in the transformer house was supplied by the Canadian General Electric Co.

In this No. 1 station, each of the 1,500 k.w. units is supplied with water from Lake Buntzen by means of a pipe line 48 inches in diameter and 2,000 feet in length. Two pipe lines 60 inches in diameter are provided for the fifth unit. One pipe line, 84 inches in diameter at the upper end and tapering to 72 inches in diameter at the power house, is provided for the sixth unit, and a similar pipe line provides water for No. 7 unit. In the original installation the first 800 feet of the pipe lines below Lake Buntzen dam were of woodstave construction. The woodstave portions of these pipe lines have now been replaced with pipes of riveted steel.

Regarding the plant No. 2 at Lake Buntzen, it may be mentioned that 4 years ago the installation of additional machines at Lake Buntzen was decided upon, and as it was impracticable to build further extensions to power house No. 1, a new power house site was found about one-third of a mile to the south of the original power house. The work undertaken in connection with plant No. 2 comprises the construction of a reinforced concrete power house containing water wheels of a total capacity of 40,000 h.p. generators and transformers, together with the necessary high and low tension switching equipment. Water for driving the units is obtained from Lake Buntzen through a concrete lined pressure tunnel 14 feet 8 inches internal diameter and about 1,800 feet long, driven through solid rock and controlled by three Doble needle intake valves placed with their seats on a concrete foundation on the bottom of Lake Buntzen. An outer cylinder is provided, which may be lowered down to a horizontal seat, thus excluding water from the needle valves, so that they may be inspected without the use of a diver. These needle valves are operated by means of oil pressure.

Engineer Conway points out that near the lower end of the pressure tunnel and close to the top of the hill, a steel surge tank 30 feet in diameter was provided, and from this point the water is conducted to power house No. 2 through three steel pipe lines. Close to the surge tank a Pelton water Doble Venturi butterfly valve is installed in each pipe line. The pipe lines are 8 feet 6 inches in diameter and ½ inch thick at their upper ends, tapering to a diameter of 7 feet at the power house, where the thickness is 1⅛ inches. About 200 feet from the power house, the pipe lines pass into tunnels driven through rock. The pipe line grades are very steep, the slopes ranging from 28 to 53 degrees, thus rendering difficult the hauling of the large pipe sections.

It will be seen from the illustrations that power house No. 2 is built on solid rock and is of reinforced concrete construction. The design of the building was carefully studied from an architectural point of view and its massive proportions harmonize with the precipitous mountains, which form the background. On the main floor of the building, which is 5 feet above high water level, three units of a total capacity of 40,500 h.p. are installed. Each units consists of one Dick Kerr 8900 k.v.a. three phase, 60 cycle generator of revolting field type, generating current at 2,200 volts, direct driven at a speed of 200 revolutions per minute by four Pelton Doble water wheels, the combined capacity of which is 13,500 h.p. The generator and four water wheels are all pressed on to a hollow nickel steel shaft 51 feet 3 inches long, forged in one piece. A separate pipe line is provided between the surge tank and the power house for supplying water to each unit. Close to the back wall of the power house this pipe line divides into four branches, each branch supplying water to one wheel of the unit; on each branch a Doble hydraulically-operated gate valve is provided, which controls the admission of water to the two nozzles which direct the water onto the buckets of each wheel.

In this station the speed regulation of each unit is controlled by a Lombard governor, which opens and closes the main nozzles according to the load on the unit, through links attached to a rocker shaft. Each unit is also provided with two Pelton Doble auxiliary relief water economizing nozzles. Should the load on the unit fall off suddenly, these two relief nozzles are opened by the action of the governor as the main nozzles are closed, thereby avoiding the sudden change of velocity in the pipe

COQUITLAM DAM

line. The relief nozzles are closed slowly by means of springs, and water hammer in the pipe lines is thus reduced to any desired extent and wastage of water is minimized. For excitation purposes, three 300 k.w. exciter units are provided, one of which is placed at the rear of each main unit. Each exciter is composed of a Dick Kerr induction motor generator set direct driven by one Pelton Doble water wheel mounted on one end of the shaft.

The busbars are placed in cells in the busbar room at the level of the main floor and the voltage is controlled by Tirrill regulators. The low tension generator and transformer switches, which are of the Canadian General Electric type, are placed in the low tension switchroom situated above the busbar compartments. The transformer room is situated immediately above the low tension switchroom, and the equipment consists of four banks of three 3,000 k.v.a. single phase, oil insulated, water cooled transformers by means of which the voltage is raised from 2,200 to 34,600, to be increased at an early date to 60,000 volts. The high tension switchroom, which also contains the lightning arrester equipment, is situated above the generator room. All of the low tension and high tension switches are electrically controlled from the operating bench board, which is situated on the operating gallery in the generator room.

LAKE BUNTZEN NO. 2 PLANT, PIPE LINES 1, 2 AND 3

SCALE

Boiler scale is very common, and more or less of it is quite sure to be formed unless the water is unusually soft and pure. It varies greatly in composition, but its chief constituents are usually sulphate of lime, carbonate of lime, and carbonate of magnesia. Chloride of magnesia and sulphate of magnesia also occur more or less frequently, and these are particularly objectionable because they are corrosive and tend to attack the metal of the boiler. The physical constitution of the scale varies greatly, and two samples of similar chemical composition will sometimes differ a great deal in hardness and porosity. Sulphate of lime usually makes a hard, stony scale when it is present alone, or when it is the chief constituent. Carbonate of lime, under ordinary conditions, forms a soft scale in horizontal tubular boilers, though it often takes a hard form in heaters and in water-tube boilers. It is rare to find a scale composed of any one substance alone, however. Various substances are usually present in it, mixed in varying proportions, and combined also with sand, clay, iron-rust, and other sedimentary deposits. Boiler scale tends to deposit wherever the circulation in the boiler is sluggish, and where the heat is greatest and the evaporation most rapid. Scale that is formed in the upper parts of the boiler also becomes dislodged from time to time, falling down upon the lower parts, where, if not removed at proper intervals, it is likely to become cemented together in a compact mass, which not only diminishes the efficiency of the boiler, but also causes it, in many cases, to become badly damaged by overheating.

WHY CONCRETE CHIMNEY STACKS FAIL

By M. E.

From the day concrete made its advent in building construction its merits were fully recognized. It must be admitted that for a large number of structures there is actually no better material than concrete. It became evident very soon, however, that it is entirely unsuitable material for any purposes where it is subject to the attack of heat, products of combustion, or undiluted acids. One of the best known structures in which such conditions prevail is the chimney.

For the moment we do not want to discuss those where the structure collapsed during construction or soon after. We refer for the present only to those which decayed very soon after being put in operation. The thin walls of the stack permitted a very rapid radiation of the heat. Condensation took place on the inner side of the stack, and the condensate worked its way into the fissures, rapidly destroying the texture of the material and attacking the reinforcing steel. The stacks started to lean, to burst open, or collapsed entirely. Recently this inherent defect has been in part overcome by using a lining of burned clay extending the full height of the stack of the chimney. In the United States of America there is little difference in the cost of a well constructed concrete stack, with a lining extending the full height, against the cost of a radial brick chimney.

Power Plant Management; Coal and Ash Handling

Various Types of Conveyors Described—Power Required For Various Types of Conveyors and Conditions Under Which They Are Operated—Pivoted Bucket Conveyors—Various Installations Described

By ROBERT JUNE

Part II.

THE power plant owner, who is considering the installation of mechanical coal and ash handling systems, is confronted by a number of fundamental problems which must all be solved correctly if he is to make a satisfactory decision. If the solutions require time and study, he will do well to refuse to be hurried in his investigations. Of all the white elephants which at times invade industrial plants, the improperly chosen conveying system is one of the largest, whitest and most voracious in appetite when it comes to eating up profits.

Prominent among the questions to be answered are the following:—

(a) What type, or types, of equipment are best adapted for the conditions in the industrial plant under consideration?

(b) Shall the coal and ash handling systems be divorced?

(c) Granted that questions (a) and (b) are correctly answered, will the equipment chosen meet the requirements of the O.M.I.-less-than-H. formula; that is, will operating costs O, which include power, labor to operate, oil, etc., plus the maintenance costs, M, which include repairs of any nature, labor required to make repairs, depreciation, etc., plus interest, I, on total money invested, which must include not only equipment and parts purchased from manufacturer, but cost of labor to install, cost of foundations, bunkers, and other changes, be less than the cost of doing the same work by hand, H.

In order to arrive at some understanding of the factors entering into the first of these three problems, we began last month a brief survey of the different types of coal and ash handling equipment. Continuing our description, we come to:

Apron Conveyors:—The apron conveyor was developed with the idea of obtaining a self-supporting continuous belt for handling heavy material. It consists of a double strand of roller chains on which are mounted steel plates, the width of which corresponds to the pitch of the chain. These plates are beaded or curved over each other to form a closed joint. The sides are also made overlapping, so as to produce a closed trough.

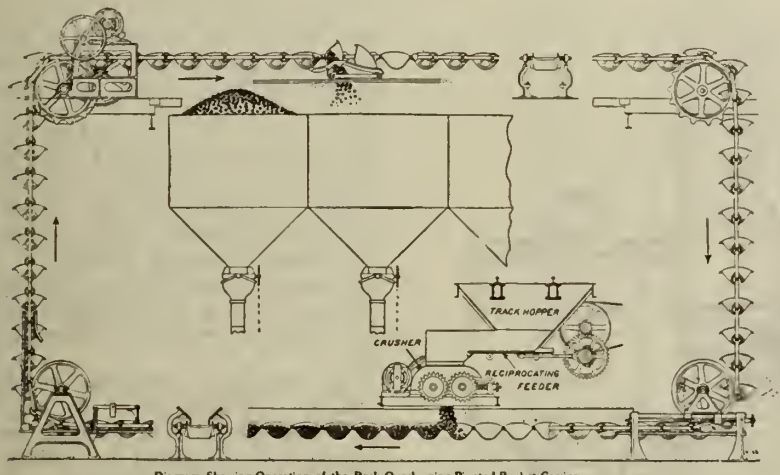

Diagram Showing Operation of the Peck Overlapping Pivoted Bucket Carrier

FIG. 1—PECK CARRIER AS MANUFACTURED BY THE LINK-BELT CO.

Apron conveyors are commonly used for conveying coal from track hoppers to the main conveyor and elevator. Only end discharge, of course, is possible, and thirty degrees inclination is the practical limit in elevation. Owing to its construction, this type of conveyor is comparatively expensive to install. However, since the load is carried and not dragged, less power is required than with the scraper type, and the maintenance is lower.

In estimating power requirements, the formula previously given for flight conveyors may be used with a reduction of 10 per cent. in the final figures.

Pan Conveyors.—In the pan conveyor, the flights are omitted and the trough itself is made in sections and mounted on the chains. By this change the material is carried, with consequent reduction in wear.

This type of conveyor is used where pans, deeper than those of an apron conveyor, are required, as on inclines too flat for elevators and too steep for efficient operation of flight, or apron conveyors. The usual speed is 30 to 50 feet per minute. When supported by self-oiling roller wheels, the power consumption is but little above theoretical load requirements. For purposes of estimate, the power may also be assumed as 10 per cent. less than that of the formula previously given.

In passing, it should be noted that on account of the abrasive character of the materials, the employment of pan and apron conveyors for ashes is apt to

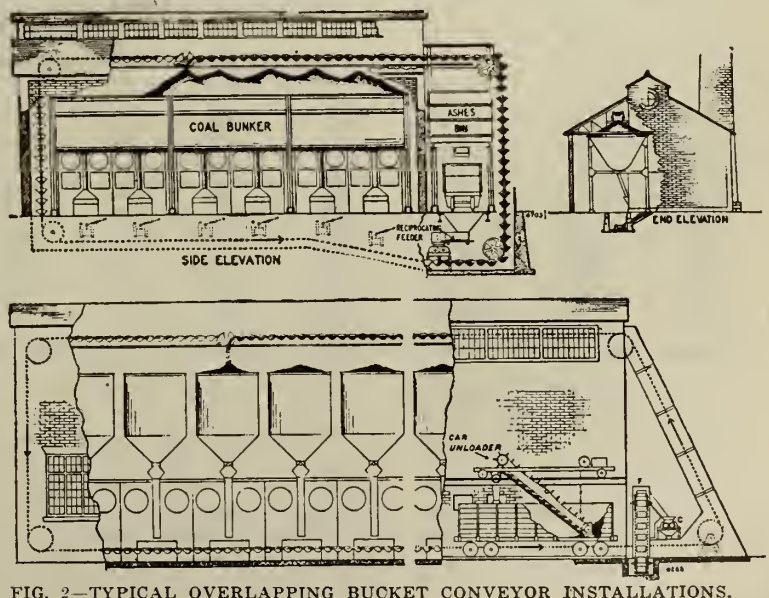

FIG. 2—TYPICAL OVERLAPPING BUCKET CONVEYOR INSTALLATIONS.

result in excessively high maintenance costs.

V--Bucket Conveyors.—In this type the buckets are rigidly fastened to the conveyor chain, with the result that on the vertical runs, the material is lifted, whereas on horizontal runs, it is dragged through the trough ahead of the bucket.

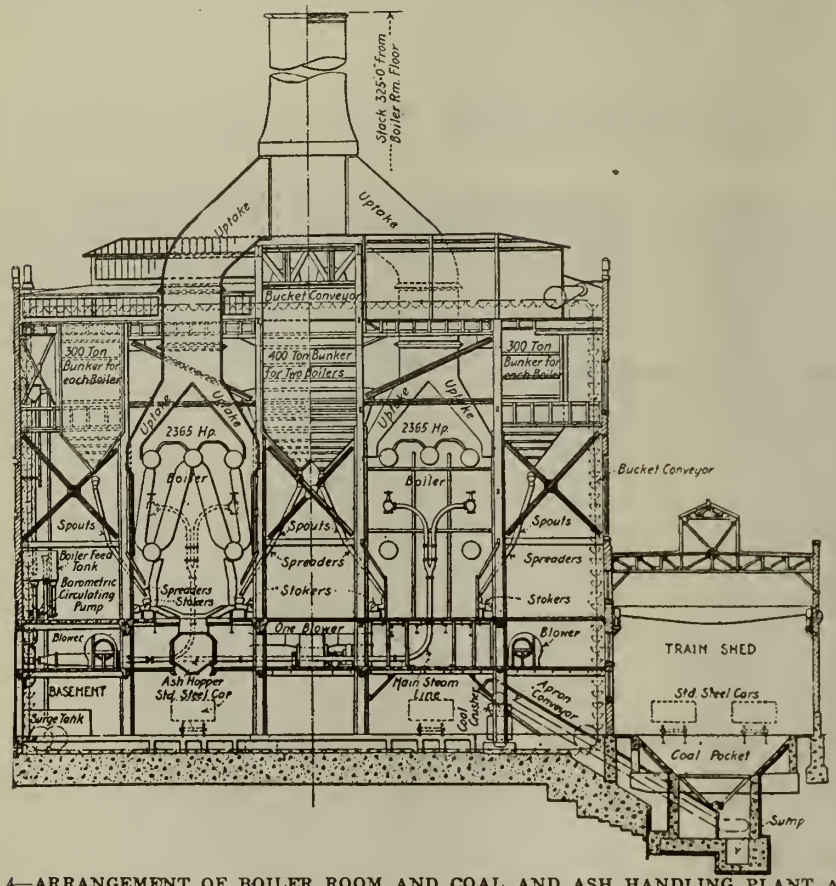

FIG. 4—ARRANGEMENT OF BOILER ROOM AND COAL AND ASH HANDLING PLANT AT THE CONNERS CREEK PLANT, DETROIT EDISON CO.

V-buckets are one of the less expensive forms of chain conveyors, and should be given consideration in the smaller power plants. While not as popular to-day as in the past, there are a goodly number of fairly representative medium-sized plants that employ them to good advantage.

Power requirements may be approximated from the following equation, supplied by courtesy of Professor Gerhart:

$$HP = \frac{AWL,S}{1000} + \frac{BLT}{1000} + \frac{TH}{1000} + \frac{1}{2} X'$$

in which

A,B—constants as in Table II.

W—weight of conveyor per ft. of run, lbs.

S—speed of conveyor, ft. per min.

T—capacity of conveyor, tons per hr. (note: figure 50 lbs. coal per cu. ft. and 40 lbs. of ashes).

L'—horizontal length of conveyor, ft.

L,—total horizontal length traversed by the loaded bucket, ft.

H—total vertical traverse, ft.

x'—number of 90 degrees turns in the conveyor.

Pivoted Bucket Conveyors.—This is the most popular form of chain conveyor for both medium and large sized power plants. The pivoted bucket carrier is composed of a continuous series of malleable iron buckets 18-inch pitch. There are several different forms of this carrier on the market. The differences in these carriers are principally in the method used to empty the buckets at the discharge point, the method used to close the gaps between adjacent buckets to prevent spillage, and the method of driving the conveyor. In one form of carrier, the buckets are made with an overlapping lip, in a second a roller is introduced between adjacent buckets, etc. The roller chain is carried and guided by a track composed of standard tee-rail. This rail is mounted on special cast-iron rail chairs, both horizontal and vertical runs. The buckets can be dumped at any desired point by means of an adjustable dump mechanism, which may be set wherever desired.

As the buckets are pivoted and always remain in the horizontal position, except when being dumped, this conveyor can be used for handling material both horizontally and vertically. The pivoted bucket carrier is generally installed in power plants, so arranged as to handle both coal and ashes in the same carrier. It is installed in the form of a loop, running through the basement, up one end of the boiler house, over the top of the overhead coal storage bunkers and down the other end to the basement. Coal is discharged from the receiving track through a track hopper, feeder and crusher, into the pivoted carrier in the basement, and carried up to the overhead storage bunkers. Ashes are dropped from the ash pits into the horizontal run in the basement and carried up to an overhead bunker for storage.

Pivoted bucket conveyors possess the following advantages:—

1. The material is carried and the buckets are supported by rollers. Destructive friction and injury to the material itself is, therefore, eliminated, and the power required for operation reduced to the minimum.

2. The ability of the one machine to elevate and convey avoids transfers, which are always troublesome, take up valuable space, and necessitate deep pits. The driving connections are also correspondingly simplified.

3. The material is readily discharged at any desired point.

4. The operation is comparatively silent, and as they are run at slow speed, there is little vibration.

Figure 1 illustrates the Peck Carrier pivoted bucket conveyor, as manufactured by the Link Belt Company. Coal is fed to the crusher by the "reciprocating feeder," which is usually placed directly under the track hopper. The

feeder consists of a heavy steel plate, mounted on rollers and having a reciprocating movement, effected by a crank mechanism from the carrier. The amount of coal delivered depends upon the distance the plate moves, and this can be varied by changing the throw of the eccentrics. The number of strokes corresponds to the number of buckets. Any size coal can be readily handled. When the distance from the track hopper to carrier is so great that the reciprocating feeder is not practicable, a continuous or "belt" feeder is used to supply the crusher with fuel. The equalizing gear" is designed to impart a pulsating motion to the driving sprocket wheel, which will counteract the natural pulsation to which long pitch chains are subject, producing violent increase of the normal strain at frequent intervals. This is accompanied by driving the spur wheel with an eccentric pinion, causing the pitch line to describe a series of undulations, corresponding to the number of sprockets on the chain wheel.

Figure 3 (supplied by courtesy of Prof. Gebhart) shows the method of handling coal and ashes in the power house of the South Side Elevated Railway. Coal is discharged from the railway cars into a track hopper and from there delivered by a "feeding apron" into a crusher, which reduces it to such a size as can be conveniently handled by the stokers. It is then discharged into a short apron or pan conveyor, which carries it to the main system of buckets and it is elevated to the proper level and discharged into the overhead bunkers. The ashes are dumped from the ash pit through a series of chutes into the lower run of buckets, by which they are elevated and discharged into the ash hopper.

In Figure 4 we illustrate the use of a combination of conveying systems at the Connors Creek Plant of the Detroit Edison Company. The coal enters the train shed in drop-bottom cars, usually of the 50-ton size. The cars dump into the hopper under the tracks in the train or coal shed, there being one hopper for each unit of one turbine and two boilers. A motor-driven variable speed flight conveyor with a capacity of 120 tons per hour receives coal from the hopper, carries it up a rather sharp incline and discharges it into a four-roll motor-driven crusher of similar capacity. This crusher breaks from 18-inch cubes, or smaller to 100 per cent. through a 1¾-in. ring.

The crusher discharges into a motor-driven variable speed hopper bucket conveyor, with 30 to 36 inch buckets. This conveyor forms an endless chain which entirely encloses the section of the boiler house. It carries the coal up on the side nearest the coal shed and discharges it into any one of the three coal bunkers which serve the two boilers of one unit.

The hopper, pan conveyors, crusher and bucket conveyors for each unit of one turbine and two boilers, are so located that they can deliver chutes to one adjacent range of bunkers, serving thus as a spare for that range.

An estimate of the power required for any proposed installation of pivoted bucket conveyors can be obtained by reference to the formula given for V-bucket conveyors, subtracting 10 per cent. from the final figures.

The use of pivoted bucket conveyors is generally regarded as the best method of conveying coal in the power plant. Unfortunately, it is probably the most expensive installation, usually requiring, in addition to the investment in the equipment itself, special boiler house construction. As local conditions may make its adoption to plants already in existence impracticable, we will take up next month the consideration of belt conveyors, hoists and mono-rail systems.

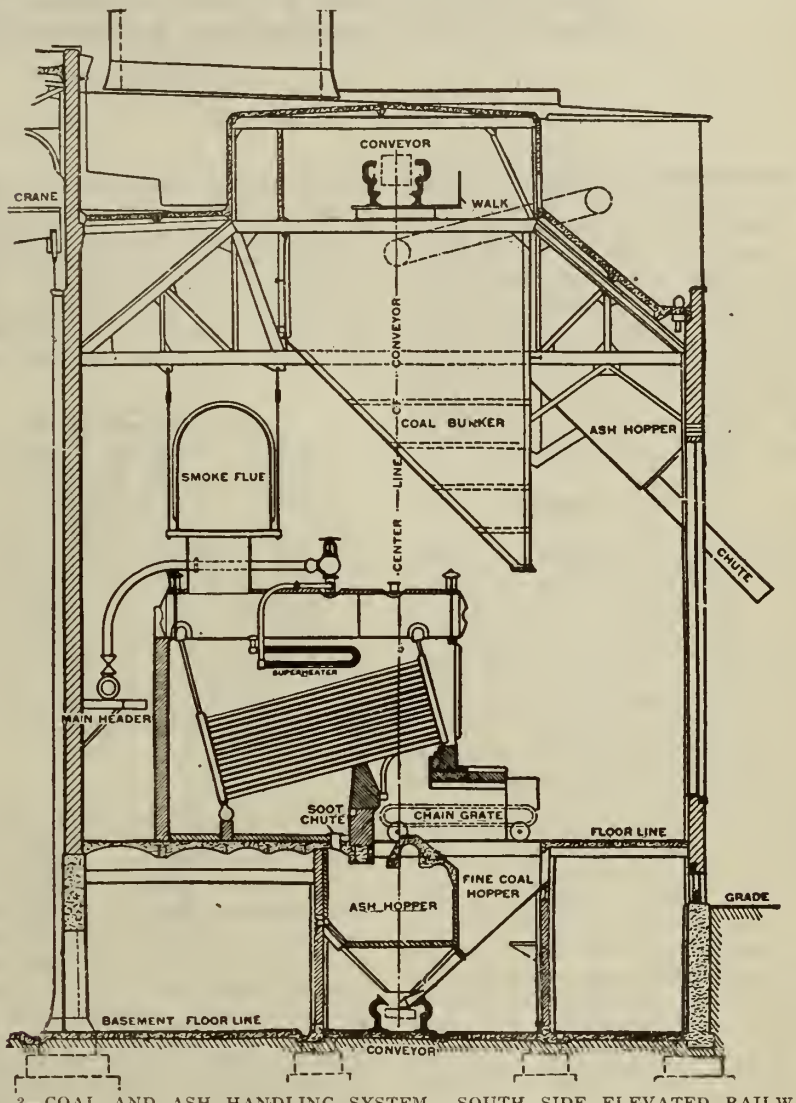

FIG. 3—COAL AND ASH HANDLING SYSTEM, SOUTH SIDE ELEVATED RAILWAY POWER HOUSE, CHICAGO

SELF-LUMINOUS PAINTS IN WAR AND PEACE

Self-luminous paints were largely used during the war for the dials of watches and instruments, for trench signs, for buoys, and many other purposes. Very little was known of the best composition of such paints and the best way of using them until Professor Clinton of University College, London, and Mr. J. H. Dow, of the Illuminating Engineering Society of Great Britain, carried out tests with a special form of electric glow-lamp photometer. They used paints made of radium bromide and zinc sulphide, which at first show a quick rise in the light given off, followed by a slow decay. They found that if more than a certain minute proportion of radium was used, the light fell away so rapidly that no advantage was gained. They also found that the same thing happened if the paint was laid on too thickly. Owing to the high cost of radium, these results enabled big savings to be affected in the expenditure on self-luminous paints during the war. They will be no less valuable in peace, when the use of these paints is developed for the illumination of instrument dials, electric switches, signs and sign posts, buoys, and other things, where it is desirable to provide permanent visibility.

Starting Rheostats for Shunt Motors

The Shunt Motor Requires a Resistance in Series With the Armature to Prevent Excessive Current—The Various Connections Used Are Described and the Size of Resistances Calculated

By TERRELL CROFT

(Copyright, all rights reserved)

RESISTANCE is required in series with the armature in starting a shunt motor, to prevent an excessive current from flowing through the armature before it has had time to commence rotation and thereby induce a counter e.m.f. Resistors of practically the same construction and connected in practically the same manner are used with series and compound as with shunt motors. With a resistance in circuit the following formula will be true:—

$$(1)\quad Ia = \frac{E - Eb}{Ra + Rr} \text{ (amperes)}$$

Wherein—Ia = current, in amp., through armature. E = e.m.f. impressed on motor and rheostat, in volts, Fig. 1. Eb = counter e.m.f., in volts, induced in the motor armature. Ra = resistance of armature circuit in ohms. Rr = resistance of starting rheostat in ohms.

At the instant when the motor is started, there is no counter e.m.f., that is Eb is then zero. Therefore, the current through the armature at this instant is:

(2) Ia = E ÷ (Ra + Rr).

Hence, at the instant of starting, enough starting resistance, Rr, must be cut in series with the armature to limit the starting current to a reasonable value—one which will not dangerously heat the machine and cause excessive sparking at the commutator. The maximum (Fig. 2) starting current permissible is usually assumed as that intensity which if exceeded would injure the motor windings, cause excessive sparking and pronounced line voltage drop. In practice the maximum starting current is limited to about 15 times normal full-load current. The minimum starting current permissible is that necessary to develop the required starting torque.

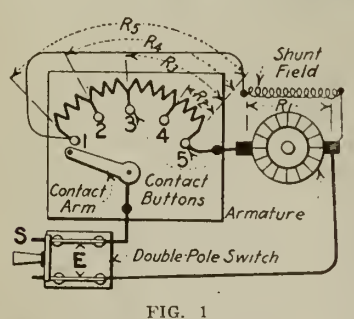

FIG. 1

Frequently the total resistance of the rheostat is made such that with all this resistance (R_6, Figs. 1 and 2) in circuit with the armature 50 per cent. of the normal starting current will flow through the armature. This is, when the contact arm of Fig. 1 is on contact button "1," one-half the normal starting current will flow as shown in Fig. 2. This current is, since it is only one-half normal, insufficient to start the motor, assuming that it must develop full-load torque to start.

When the arm is moved to button "2" the rheostat resistance then in series is such that the normal starting current

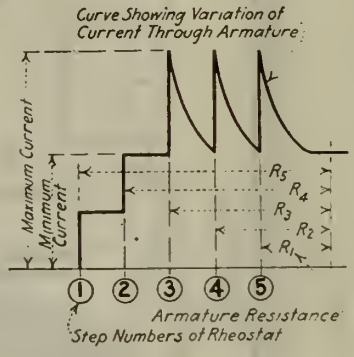

FIG. 2

flows through the armature as shown in Fig. 2. This may not be a great enough current to start the load. But when the arm is moved to button "3" the maximum permissible current will be forced through the armature from the line and the load should start. As the motor increases its speed its counter e.m.f. increase and the current decreases, as shown in the diagram of Fig. 2. The contact arm is then shifted successively over the other contact buttons until its rests on button "5." Now all of the rheostat resistance is cut out, the only resistance in the armature circuit being that (R_1) of the armature itself, because the motor armature is now inducing a sufficiently height counter e.m.f. to itself limit the current through the armature.

A starting rheostat for a shunt or compound motor, or as it is usually called "a starting box," is an apparatus wherein are assembled the devices essential for the starting of the motor and frequently also those for the protection, after the motor is in operation, of it and of the circuits which feed it. The term "starting rheostat" as it is commonly used implies more than merely an adjustable rheostat. Fig. 3 shows diagrammatically a "starting rheostat" of the simlest type. There are numerous variations in practice to satisfy the many possible conditions. See the author's *American Electricians' Handbook* for detailed descriptions. A commercial shunt or compound motor starting rheostat usually comprises:—*First.*—An adjustable resistor or starting rheostat pure and simple, the function of which is to limit the armature current at starting as described above. *Second.*—A no-voltage release, described below. *Third.*—A no-field release, described below. *Fourth.*—An overload release, described below. This device is frequently omitted.

The operation of starting a shunt motor is as follows: The line switch is closed, impressing the line voltage across brush B and metallic swinging arm C (Fig. 3). Then the arm is moved up to contact with button 1. This connects both the armature and the field circuits to the line and current is forced through each. The current through the armature, which is small, being limited by the starting resistance as described above, flows via the route:—L_1, L, C, 1, 8, A, B_2, B, D, L_2. The path of the field current is:—L_1, L, C, 1, M, F, W, D, L_2.

Note then, that when the arm is on the first button, a small current flows through the armature and that the field winding is connected directly across the line (magnet winding M is in practice of very low resistance as compared with the resistance of the shunt-field winding). So the field is strong—a maximum—and the armature current weak. Now the arm is moved successively over buttons 2, 3, 4, etc., with a pause at each button. The current through, and the torque of, the armature will be thereby gradually increased as described above.

It will be noted that the armature resistance is inserted in the field as the arm advances, but the field is weakened only slightly because the rheostat resistance is very low compared to that of the field. This weakening of the field tends to assist in speeding up the armature. From 15 to 30 seconds should ordinarily be consumed in starting a motor.

Finally, the arm is moved to contact with button 8 where it is held by the attraction of magnet M on iron keeper K, which is attached to the arm. The field current energizes M, the functions of which are treated in detail below. With the arm on 8, the armature is connected directly across the line and the field winding is across the line in series with M and the starting resistance. The combined resistance of the *starting resistance* and M in series is small as compared with the resistance of the motor field winding. Hence, the shunt-field strength is affected little thereby.

To stop the motor, pull the line switch. Magnet M will then be demagnetized and spring S will force the arm back to its original position shown in the illustration.

A no-voltage release device is provided on motor starting rheostats to protect the

motor and the circuits feeding it against an excessive rush of current in case the line e.m.f. is discontinued and is then again impressed on the motor without the starting-rheostat handle having meanwhile been returned to the starting position.

Explanation.—Assume that the starting rheostat of Fig. 3 is not equipped with

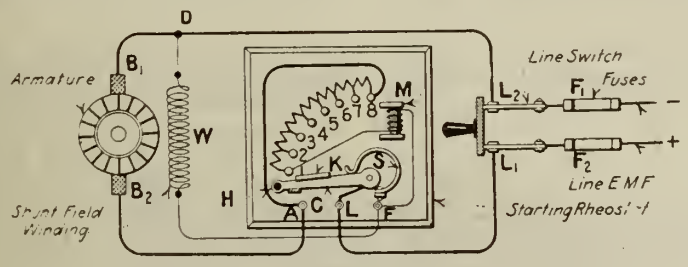

FIG. 3

the no-voltage release magnet M or the spring S. Then, if the lever arm C were moved into contact with button 8, the arm would remain in that position, even if the line e.m.f. were discontinued from any cause. Assume that the arm is in contact with 8, that the line e.m.f. is discontinued and the motor armature slows down or ceases to rotate in consequence. Now if the e.m.f. is again impressed on the line, C still on 8, there would be very large current forced through the armature, because it would be turning slowly or at rest and, therefore inducing little or no counter e.m.f. This excessive current would cause sparking at the commutator and might damage it or "burn out" the motor windings or the wiring.

But with the no-voltage release magnet M arranged as in Fig. 3, when the line e.m.f. is discontinued and the armature ceases rotating, M is demagnetized and C is forced back into the "off" position by spring S. Then the circuit through the motor is open and the resumption of line e.m.f. can do no harm.

A no-field release device is provided on motor starting rheostats to prevent the armature remaining connected to the line in case the motor field becomes weak or ceases to exist. Frequently, as in the diagram of Fig. 3, the same magnet, M, answers for a no-voltage and a no-field release.

Explanation.—With a weak field the armature speed will become excessive. An armature rotating at a speed much in excess of that at which it was designed to operate may have its windings torn off by centrifugal stresses. With no field at all, the armature will cease rotating, and, there being no counter e.m.f., a dangerous current will be forced through it. However, with the holding magnet M (Fig. 3) connected in the shunt field circuit, if this circuit opens or the current through it becomes too weak, iron keeper K will be released and arm C will be forced back to the "off" position, thus opening the circuit.

An overload release on a starting rheostat is sometimes provided to prevent excessive current flowing through the motor or wiring, if the motor is overloaded or if a short-circuit or similar trouble occurs on the motor circuit. Circuit breakers and fuses perform functions similar to that of the overload device and are frequently substituted for it, because they may protect both sides of the circuit (F and F_2, Fig. 3). Usually the overload device described below protects only one side of the circuit.

Explanations.—Fig. 4 illustrates the principle of an overload release device of one type. The holding magnet M is the same one as in Fig. 3. The overload release magnet is shown at S. The low-resistance winding of the magnet is in series in one of the line wires of the rheostat so that the motor current actuates it. This magnet S is so proportioned that if a current greater than that which the motor and circuits can safely carry flows through it it will attract the iron keeper I which is attached to the metal arm Q. This will raise Q into connection with contact points P, and P_2. Thus a shunt or short circuit is established around the winding of M which is thereby demagnetized. Then the keeper K (Fig. 3) which M was holding will be released and arm K will be forced back to its "off" positions, opening the motor circuit.

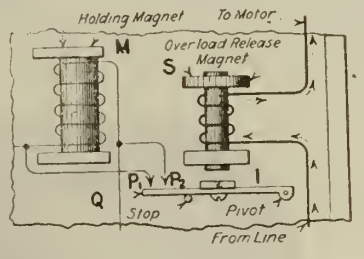

FIG. 4

A PROBLEM IN LUBRICATION

By M. E.

Mr. W. B. Hardy, M.A. (secretary of the Royal Society), discussed the problem of lubrication in relation to colloids. Water, ether, alcohol, benzine, and strong ammonia were apparently entirely incapable of maintaining a lubricating film on glass. "Seizing" occurred just as readily when they were present as it did with cleaned surfaces. Glycerine differed from those fluids in the fact that, though it would not maintain a lubricating film, it did prevent "seizing" when present in excess. For instance, the maximal tangential force which a pair of cleaned surfaces would support without slipping was measured in grammes 55. Flooding the surface with water, benzine, alcohol, etc., left that value unchanged. When a film of glycerine was deposited on the surface the force stood at 55, measured in grammes, but it fell as the quantity of glycerine present was increased to 9, when the surfaces were fully flooded. The expression "film" denoted a layer of fluid on the solid surface, so thin as to comprise probably only a single layer of molecules. With a true lubricant the facility for slipping was maximal when a layer of such excessive tenuity separated the solid faces and nothing was gained by increasing the thickness of the layer. Thus with castor oil the weight required just to start one face of glass slipping over another was 10 grammes, when only the invisible film of fluid mentioned above was present, and it was still 10 grammes when the surfaces were flooded with oil. Some fluids indeed seemed to lubricate better in thin than in thick layers; to act, that is to say, in the contrary way to glycerine. Acids as a class behaved in that way, the solid faces again being of glass. The pull in grammes was as follows:

	Film	Surface flooded
Acetic acid	40	47
Sulphuric acid	37	47
Oleic acid	10	13

If that result could be fully substantiated it would be an important and striking physical fact likely to throw much light upon the process of lubrication.

One broad conclusion emerged—namely that lubrication depended wholly upon the chemical constitution of a fluid, and the fact that the true lubricant was able to render slipping easy when a film of only about one molecule deep was present on the solid faces suggested that the true lubricant was always a fluid which was absorbed by the solid face. If that be so, then the problem of lubrication was merely a special problem of colloidal physics.

GOOD ENGINEERS AND FIREMEN

It is hard to exaggerate the importance of having good men in charge of the boiler room. The unskilled man usually proves expensive. He is wasteful of fuel and of other supplies,—not intentionally, but because he is careless or unskilled. There is also a large chance that the inferior man will damage the boilers and machinery under his care, by incompetence or neglect; and many costly boiler explosions have resulted from failure to do something or other in the right way, or at the right time. Sometimes the authority to hire the men, or to determine what shall be paid to them, rests with the wrong person.—with a person, namely, who does not appreciate that while a clerk can usually waste nothing but his own time, a boiler-room attendant can not only waste tons of coal in addition, but can also endanger the whole plant. A mistake of this kind should be promptly rectified, by giving more authority to some one who has a better understanding of the boiler-room problem.

The owl has no power of motion in its eye, the globe of which is immovably fixed in the socket by a strong, elastic, hard, cartilaginous case, in the form of a truncated cone; but in order to compensate for this absence of motion in the eye it is able to turn its head round in almost a complete circle without moving its body.

The Principles of Two-Stage Air Compression

Adiabatic and Isothermal Expansion Defined—Advantages of Two-Stage Compression—Function of the Intercooler and Its Design—The Removal of Moisture

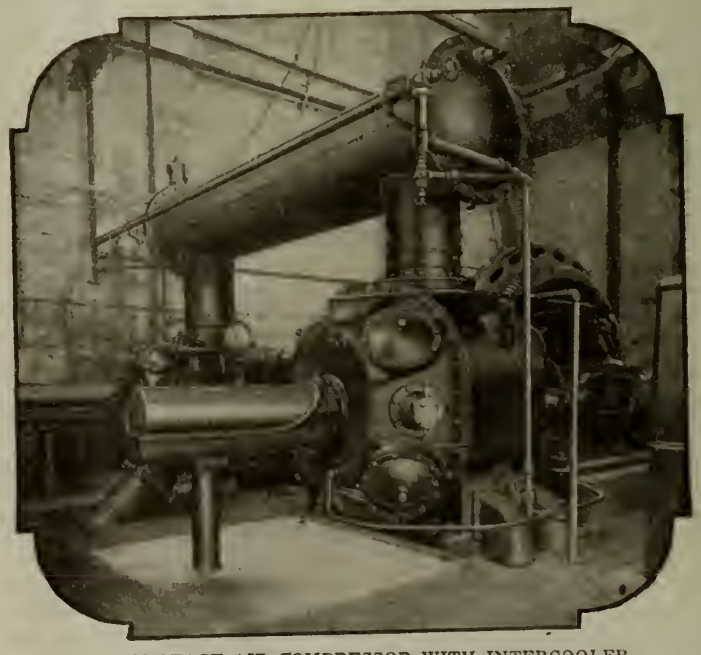
By A. W. SWAN

IN the literature of compressed air there are two terms continually appearing of rather terrifying appearance, "isothermal" and "adiabatic." However, one long word expresses the meaning of a whole sentence of shorter words, and this is the case with these two expressions. Speaking of air compression, "isothermal compression" means "compression with no increase of temperature"; "adiabatic compression" means "compression without loss of the heat generated by the compression." The terms "work" and "heat" are interchangeable, and if air is compressed without any chance for the heat to escape the temperature of the air will increase. In actual compressor practice a certain amount of the heat does escape, but the compression is so rapid that in the ordinary air compressor the compression is nearer the adiabatic (increasing temperature) than the isothermal (same temperature).

There are a number of reasons why the heat of compression should be removed if possible. Air expands when heated, hence if a compressor delivers 1,000 cu. ft. of air at 485 degrees (the temperature of adiabatic compression to 100 lbs. gauge), on cooling to atmospheric temperature the actual delivery will be considerably less than 1,000 cu. ft., so that to have an actual delivery of 1,000 cu. ft. the compressor will have to take in more than this amount, and the power to drive the compressor is correspondingly increased. Hence the lower the delivery temperature the greater the saving in power to drive the compressor. This is by no means the only gain from low delivery temperature; with a temperature such as 485 degrees there is considerable danger of spontaneous ignition of even the best lubricating oil; also the sudden extremes of temperature succeeding each other so rapidly have a harmful effect on the cylinder and piston, and hasten wear.

Compressor efficiency, therefore, depends on the degree to which the heat of compression is removed. Jacket cooling is necessary to keep the metal of working parts at a reasonable temperature, and to prevent the coking of the lubricant, but is not very efficient in removing heat from the air as it is being compressed for two reasons. In the first place air is a very poor conductor of heat, and in the short time of compression in the cylinder only the film of air next the cylinder wall has time to be cooled. Further, the amount of cooling surface becomes smaller towards the end of the stroke when it is most needed. The most efficient method of removing the heat of compression is by splitting the compression into two stages and cooling the air between the stages in an "intercooler." By this means the air does not reach an excessive temperature in either stage; it is delivered at a temperature considerably below the lowest possible with single stage compression with the most careful jacketing, and the resulting economy is correspondingly great. Additional advantages come from the fact that the temperatures in the two cylinders are not high enough to cause danger with the lubricant (and allow the use of ordinary lubricant where a special grade would be necessary to cope with the excessive temperatures of single stage compression). Then again the lower temperatures are beneficial to the wear of the machine, the compounding gives better balance, and the stresses are not so high as with single stage compression.

With such a list of advantages for two-stage compression, it is not surprising that for pressures above 80 lbs. gauge, as a rule only the smaller air compressors are built single stage.



TWO-STAGE AIR COMPRESSOR WITH INTERCOOLER

The success of the two-stage compressor in securing economy greater than that given by single-stage compression depends to a large extent on the design of the intercooler. The intercooler consists of a receiver containing a nest of tubes, through which flows cooling water. From the discharge valve of the low pressure cylinder the air passes through the intercooler, where it is cooled by contact with the cold water pipes. It has been found that the saving in power due to two-stage compression is about one per cent. for every ten degrees of cooling. From this it follows that the design of the intercooler plays a very important part, as the more effective the cooling the greater the saving in power. For instance, if the atmospheric temperature is 60 degrees, and the first stage of compression is to 25 lbs. gauge, then the temperature of the air after the first stage of compression will be about 230 degrees. If the cooling in the intercooler is to 70 degrees (about the best possible in practice), the saving in power will be 14 per cent. over single stage compression, while if the cooling is only to 90 degrees, the saving will be only 12 per cent.

The requirements of the efficient intercooler have been summarized as follows:—

1. The air in passing through the intercooler should be very thoroughly subdivided. Air is a very bad conductor of heat, and every part of the air should have as much contact as possible with the cooling surface.

2. The velocity of the cooling water would be such as to remove heat from the air with the minimum waste of water. The water supply is sometimes a serious problem.

3. The air passages should be such as to give the correct air velocity.

4. Expansion and contraction due to

changes in temperature should be provided for in the intercooler shell and tubes; if this is not done, leakage of air or water will result.

5. There should be a moisture trap to remove all the moisture deposited by the cooling of the air. The removal of moisture is one of the principal benefits of intercooling; the dryer the air, the less the chance of freezing in the hoist, pneumatic tool, or rock drill.

6. The intercooler should be of ample size; acting as a receiver between the stages the intercooler steadies delivery

The moisture trap is seen at "M" in the figure.

At first sight it would seem that the ideal material for intercooler tubes would be brass or copper in preference to iron, as these are better conductors of heat. However, when it is considered that air is a very poor conductor it is easy to see that it is far more important to have the air in the intercooler brought into frequent and intimate association with the cooling tubes than to have the tubes of material having good conductivity. This is borne out in Kent's

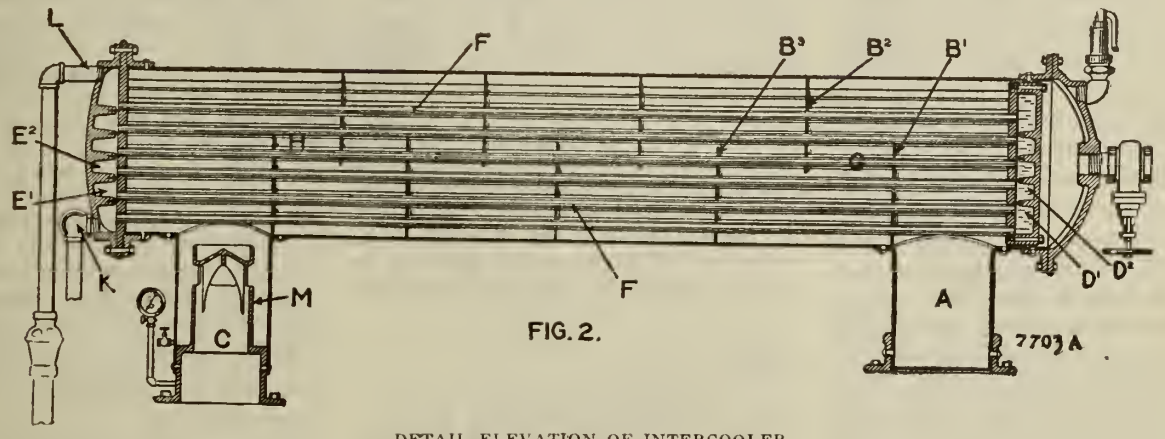


FIG. 2.

DETAIL ELEVATION OF INTERCOOLER

These requirements are shown in a discussion of a standard intercooler (intercooler for PRE-2 Compressor of Ingersoll-Rand). For ordinary pressures this consists of a shell containing a nest of tubes, inside which the cooling water flows. Air enters from the low pressure discharge at A, passes up and around the baffle plate B1, down and under baffle plate B2, over B3, etc. The air is thus taken up into a number of small streams, and by means of the baffle plates is forced into contact with the water tubes a large number of times.

The velocity of the cooling water is important. In a comparative test between this intercooler and an earlier model of the same company, the more modern intercooler averaged one-third less water consumption for the same cooling, and was able to cool the air to a point not reached by the older model.

There is considerable dispute as to the correct velocity of the air as it passes through the intercooler, but a mean speed must be found between that at which an appreciable drop is caused in pressure, and that found too low for thorough cooling. As the air cools it decreases in volume, and to keep the air speed constant, good design places the baffle plates nearer together at the high-pressure (cool) end of the intercooler, as can be seen in the illustration.

To secure free expansion, one tube-plate (the right-hand in the illustration) is free, while the other is attached to the shell. The free end is able to slide back and forth with changes in temperature without any strain or leakage; water connections are, of course, made at the fixed end of the intercooler.

Handbook, where it states that: "Taken generally, the results of these experiments show that there are practically but slight differences between iron, copper, and lead, in evaporative activity. Mr. W. B. Johnson formed a like conclusion from the results of his observations of two boilers of 160 h.p. each, made exactly alike, except that one had iron flue-tubes and the other copper flue-tubes. No difference could be detected between the performance of these two boilers.

THE THERMOMETER

The word "Thermometer" is a combination of two words, thurmo being taken from the Greek word "Thurmos," meaning "heat," and meter is a measure. A thermometer is therefore a heat measure, or, more properly speaking, an instrument for measuring intensity of heat, or temperature, by means of expansion of a liquid or gas. Mercury is generally employed, and an ordinary thermometer consists of a spherical or cylindrical glass bulb at the end of a very fine tube, the bulb being completely filled, and the tube partly filled, with mercury, whilst the space above the mercury contains only a small quantity of mercury vapor, which offers no resistance to the expansion of the mercury. A rise in temperature, which simply means that the atmosphere or air has absorbed more heat, is indicated by a rise of the mercury in the tube, owing to expansion, and conversely a fall of temperature is indicated by a fall of mercury in the tube.

A graduated scale is attached with two fixed points: the lower, or freezing point, and the upper, or boiling point of water. The distance between the two fixed points is then divided into a certain number of equal parts or degrees, which are continued above and below the two fixed points. On the Celsius or Centigrade thermometer (used by scientific men everywhere, and in general use in Continental Europe), the distance between the two points is divided into 100 degrees, the freezing point being 0° and the boiling point 100°; on the Fahrenheit thermometer (used in England and America) the distance is divided into 180 degrees. With the Fahrenheit thermometer the boiling point would therefore be 180° above the freezing point, but since zero or 0° is not at the freezing point, but is 32° below at the point where salt water freezes, the boiling point is 212° above zero. The two systems make it very confusing to one not accustomed to both. In this country everyone is familiar with the Fahrenheit thermometer, but occasionally a scientific article appears where the centigrade degree is used, being marked °C, and before it can be understood by the ordinary Canadian layman it has to be translated into Fah. To do this it is simply required to multiply the number of centigrade degrees by 9 and divide the result by 5 and add 32. This will be understood because 100 degrees C = 180 degrees Fah. A degree Fah. is therefore one hundred, one hundred and eightieth, or five-ninths of a degree C., and vice versa, a degree C is nine-fifths of a degree F. If the temperature is 100°C we multiply it by nine-fifths, which makes it 180° Fah. above the freezing point or centigrade zero, and by adding the 32° we make it 212° Fah. above the Fahrenheit zero.

Centigrade is taken from centum, meaning 100 and grade relating to the graded or graduated scale. Fahrenheit is the name of the man who originated that system.

It is said that 21,000,000 yards of burlap could be saved if fertilizer dealers would abandon the use of the 100-pound bag and made use of the 200-pound bag instead. On account of the general use of burlap in shipping articles of food now being sent abroad, there is a great scarcity of burlap.

The Securing of Economy in the Burning of Fuel

The Process of Combustion—The Influence of Draft on the Burning of Coal and the Use of Draft Gauges—The Importance of Eliminating Air-Leaks

By J. F. PATTON

DURING the process of combustion of coal in a furnace the combustible elements, carbon, hydrogen, and sulphur combine with oxygen, forming carbon dioxide, steam, and sulphur dioxide respectively. Air by volume is 21 per cent. oxygen and 79 per cent nitrogen, the latter being an inert element of no value in this work. During combustion heat is driven off, and if one pound of carbon is burned to carbon dioxide 14,600 B.T.U. will be released. For every pound of hydrogen turned to. steam or water vapor 62,100 B.T.U. are released while 1 lb. sulphur releases 4,000 B.T.U., when changed to sulphur dioxide. This liberated heat is used in several ways, part raising the temperature of the fuel bed, part going to surrounding surfaces, and still another part raising the temperature of the products of combustion. The heat carried away by the gases represents a distinct loss as it does no work and, in addition to being inert and of no heating value, the nitrogen acts as a carrier and absorber of heat, as its own temperature is raised before it escapes. During the process of combustion one pound of carbon forms 3.67 pounds of carbon dioxide, which is composed of 12 parts carbon an parts oxygen by weight. Therefore 32/12 pounds of oxygen will be necessary to burn 1 pound of carbon or $32/12 \times 1 = 2.67$ pounds of oxygen are needed. Ordinary air contains but 23 per cent. oxygen and in order to obtain 2.67 pounds of oxygen, $2.67 + .23 = 11.6$ pounds of air is required. As 11.6 pounds of air are used and only 2.67 pounds are oxygen we therefore, have a waste of $11.6 - 2.67 = 8.93$ pounds nitrogen.

When hydrogen burns the product is H O or water, which is 2 parts hydrogen and 16 parts oxygen. To burn 1 pound of hydrogen it is necessary to use $16/2 \div 8$ pounds of oxygen. To obtain 8 pounds of oxygen $8 \div .23 = 34.8$ pounds of air is required. Eight pounds of this are used and almost 27 pounds passes up the chimney without aiding combustion. When burning sulphur we form SO_2 which is 32 parts sulphur and 32 parts oxygen. This makes it necessary to use 32/32 or 1B. of oxygen to burn 1 pound of sulphur. In order to obtain 1 1B. of oxygen $1 \div .23 = 4.35$ pounds of air must be burned. It is evident that if the percentages of carbon, hydrogen and sulphur are known the air necessary to completely burn 1 pound of coal will consist of 11.6 times the weight of carbon $\div$ 34.8 times the weight of hydrogen 4.35 times the weight of sulphur For average coal this will be about 12 pounds of air to one of coal. It is also evident that the air supply should be watched very carefully if efficient operation is obtained, owing to the enormous amount of nitrogen which passes through the furnace.

Any air above the chemical requirement for complete combustion is known as excess air and as every cubic foot of oxygen used is replaced by a cubic foot of CO_2 or carbon dioxide the percentage by volume of this gas in the flue may be used to indicate the state of combustion.

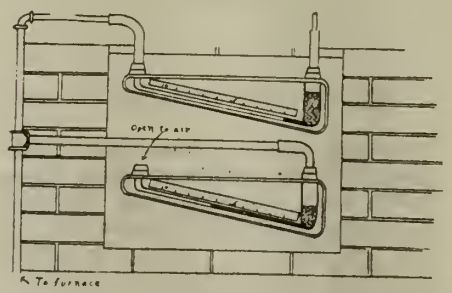

FIG. 1— DRAFT GAUGE

If just enough air is supplied to insure the complete combustion of the carbon, the oxygen will be replaced by the CO_2 and the percentage of CO_2 by volume in the mixture will be the same as the percentage of original oxygen. If twice as much air is used as is necessary the same amount of CO_2 will be formed, but this will replace only ½ of the oxygen, and therefore its percentage will be only ½ as great as in the former case. If the air supply is insufficient the carbon cannot combine and form CO_2 but form CO, or carbon monoxide, as this uses but half as much oxygen, and in this case there is a great difference in the amount of heat liberated, as one pound of carbon burned to CO_2 gives off 14,600 B.T.U.,but only 4,500 B.T.U. wen CO is formed. As this represents an enormous heat loss the per cent. of CO must be kept as low as possible.

In perfect combustion every particle of carbon must come in contact with the proper amount of oxygen, therefore to insure this contact a slight excess of air is necessary.

Draft as used in connection with this work does not mean the motion of the air in the stack or through the fuel bed, but the difference in pressure inside and outside the stack. When there is an opening into the furnace this difference in pressure will force air into it. the amount depending on the condition of the fire and the resistance offered to the air flow. Every boiler should be equipped with two draft gauges, one connected directly into the space above the fire. the other into this space as well as the gas passage below the damper, as shown in figure 1, as this will give the drop in pressure through tubes and baffling. The draft over the fire should be used in controlling the fire and when everything is in good condition there should be a definite loss in draft through the setting. Any increase in this loss will indicate holes in the fuel bed or that the tubes are clogged. A decrease will indicate a dirty fuel bed or the presence of clinkers or excessive ash.

The only practical means of determining conditions inside is by a study of the flue gases. Every plant should be equipped with apparatus for making a CO_2 analysis. One type is shown in figure 2. It consists of a glass retainer "A" for the liquid, which may be a solution of equal parts of potassium hydroxide and water or of concentrated lye; a graduated glass "B" which holds exactly 100 cu. centimeters; a bottle containing water and a rubber bulb "P" with the necessary pipes and tubing.

When this is used, first bring the liquid in A to the mark "M" just below the cock D. This is done by lowering the bottle C. The cock D should then be closed. The cock E operates three ways and should now be opened to glass B and to the air through F. By raising the bottle, the water in the glass is brought to the mark H at the top of the glass, then the cock is closed to the glass but opened to the sampling pipe and the air. The dead air should now be blown out by working the bulb, then close the cock to the air at F and open it to glass B. A sample of the flue gas is now pumped until the liquid in the glass stands at 100 C.C., then grasp tubing between the bottle and the glass so that there can be no change in the liquid in the glass. The cock is now momentarily opened and the liquid in the glass and bottle again leveled, and the gas driven into A by raising the bottle. Drive back and forth several times, then stop when level in B is exactly at 100 C.C. The cock is now closed and the level of the liquid in B and C brought to the same point.

The percentage of CO_2 may now be read directly on the graduated glass.

Proper precautions should be taken to

eliminate all air leaks as even a slight leak will invalidate the result. The apparatus should be hung on the setting at a point as near as possible to the point where the sample is taken, as the object is to determine what the fire is doing, and it is important that short connections be used, as this reduces the time which elapses between the time of taking the sample and the determination of the result. No elaborate sampling apparatus is needed. One frequently used consists of a double tube arrangement extending across the gas passage, holes being drilled into the tubes. This is not reliable as the holes may become clogged with soot, which makes it impossible to determine the exact point from which a sample is drawn. It is best to take a sample through the end of a straight tube consisting of a piece of ¼ inch gas pipe. When this is used the point of sampling may be known with accuracy. Great care should be taken to place the end of the tube in the exact centre of the main gas stream as shown at 2 in figure 3 and not in any of the dead gas pockets as shown at 1 or 3. Samples taken from the latter places will not show representative CO_2 values. The tube should always be inserted at the point when the gas stream leaves the heating surfaces for the last time. Care should also be taken not to heat the end of the tube to redness as this will invalidate the reading, as some of the carbon in the iron will combine with the oxygen in the flue gas. It is also well to use a small cloth filter between the sampling tube and the bulb, and the entire apparatus should be protected from drafts while the experiment is being performed. This test is easily executed and can be completed in two minutes' time by an average fireman with only a little training.

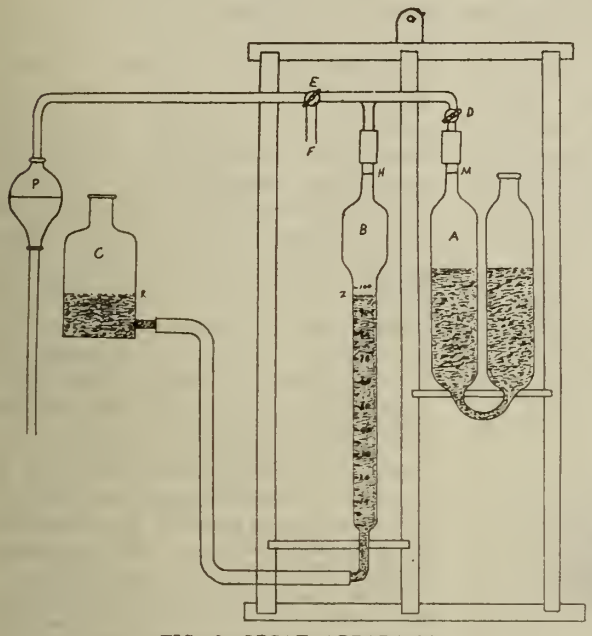

FIG. 2—ORSAT APPARATUS

There is always a very definite relationship between draft, capacity, fuel bed thickness, and air passing the fuel bed for every grade of coal, and the efficient engineer will determine these for his own particular plant. Before making a test it is well to see that there are no air leaks through the setting. The test should be made at a time when a constant load may be expected for a considerable time. The fire must be clean and the fuel bed of even thickness and all the tubes clean. Assume a draft and fuel bed thickness sufficient to carry the load without loss of pressure, then take simultaneous readings of the draft gauge and CO_2. Repeat these as rapidly as possible, keeping records of all readings. The fuel bed should now be varied and the draft adjusted so the load may be carired without loss of pressure. When these conditions have become constant another set of readings should be taken, and so on. If, on starting the test, the fuel bed is too thin, the draft and CO_2 readings will increase as the thickness of bed increases, but in every plant a point will finally be reached when an increase in the bed does not result in any increase in the draft or CO_2 percentage, and this represents the proper values for the given load. The test should be repeated with different loads within the daily range of the plant. These will show that with a given load certain well defined limits of draft give maximum CO_2 readings and the draft therefore becomes the key to the entire situation. When the load requires a certain draft then the proper thickness of fuel bed is known, provided the fire is kept clean, free from holes, and the tubes are clean. These latter conditions can be determined from differential draft gauge readings as shown in figure 1, which should be taken with the other readings of the test. A chart can easily be made for the direction of the fireman, the following of which will result in efficient plant operation.

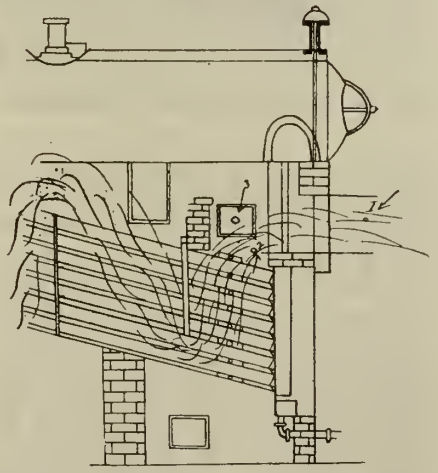

FIG. 3—DRAWING GAS SAMPLES

ELECTRIFYING ITALY'S RAILWAYS

Great savings in the use of coal, according to the Italian Bureau of Public Information, have been effected in Italy in the past few years through the electrification of railroads and harnessing the water power of the country to generate electricity. The percentage of railroads electrified in Italy from 1900-1915 is greater than in any other European country, and the economies resulting have been gratifying.

Electric traction of railroads began in Italy in 1900 with installations on the Varesina Line, which runs through Milan, Gallarate, Varese and Ponteceresio, and on the Valtellinese Line, which runs from Lecco to Chiavenna.

Railways which run on mountainous routes and carry heavy trains have been installed with different systems. The principal mountain routes electrified are the Moncenisio line, the Ceva-Port Savona line, the old line of Giovi, and the new supplementary Giovi line. These cover some of the most difficult territories traversed by any of the railroads in Europe.

The Moncenisio line is the longest of the mountain railways. It is 8.5 miles long, travels at an altitude of more than 1,000 yards above sea level and is continuously on the ascent. It has a nominal carrying capacity of 640,000,000 tons per mile, and actually carries 240,000,000 tons. The Ceva-Port Savona line is a series of steep inclines and declines. The Giovi line has the most rapid descent of any railroad in Europe and the supplementary Giovi line carries the heaviest traffic in Italy.

The perfect systems installed on these mountain routes have made possible the increase in the carrying capacity and the speed of the railways. There is at present under consideration the electrification of 1,250 miles more of railways.

DESTRUCTION TESTS OF ELECTRIC PLANT

Tests to destruction are occasionally used in engineering works to discover how much ill-treatment a machine will stand and which part is really the weakest. During the war every electric power station in Great Britain has been subject to very much the same kind of treatment. Thanks to the tremendous demand for electric power in munition works (ninety-five per cent. of these works were driven electrically) all the plant in the generating stations, boilers, dynamos, switchgear, transformers, and mains, was overloaded to a pitch which might well have meant destruction. The manner in which the plant stood up to this long and exacting ordeal is a magnificent proof of the sound design and construction of British electrical machinery and appliances. The difficulties were increased by the fact that, owing to the night and day demand it was generally impossible to overhaul the plant. In one typical case most of the boilers in the station had not been cleaned for a year. Now that this tremendous strain is relaxed British engineers realize that their electrical machinery has done better than ever they, in their most sanguine moments, would have expected it to do.

Water Pumping Water

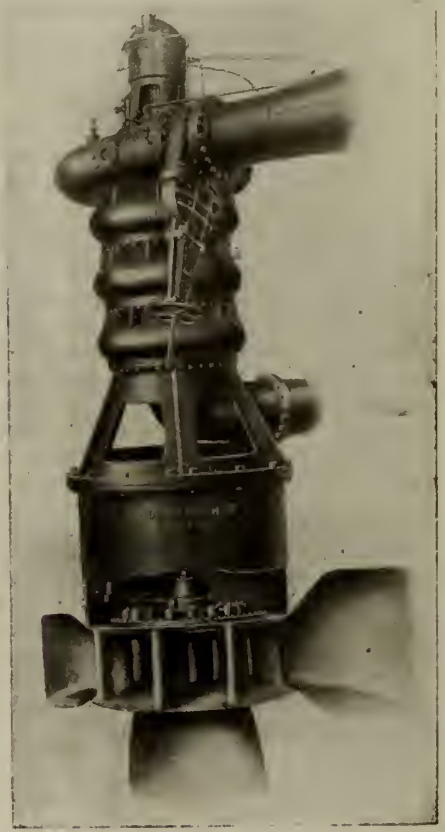
THE accompanying illustration shows the power and pumping equipment for the Grandview Irrigation District at the Sunnyside Unit of the Yakima Project at Washington. This plant is located at the head of the Mabton Feeder Canal, approximately two miles from the town of Grandview, on the Sunnyside main canal, and contains one direct connected turbine-driven pumping unit and two motor-driven units. All three units receive water from the Sunnyside main canal.

In this scheme, in which the water-power pumps the water for irrigation, the water which is used for operating the hydraulic turbine is discharged into the Mabton Feeder Canal, while the water which passes through the pumps is discharged through woodstave pipe lines to high line canals. The net power head under which the hydraulic turbine operates is 21 feet, while the working head against which the pump operates is 78 feet. The water is discharged through 6,000 feet of 40-inch inside diameter woodstave pipe, the maximum velocity in this pipe being 3 feet per second. The horizontal centre line of the turbine unit is placed 7 feet above tail water and 4 feet below the floor of the pump house. The turbine is installed in a closed concrete scroll and discharges through a concrete elbow-shaped draft tube.

It will be seen that the turbine consists of a vertical shaft 30-inch wicket gate unit, which under 21 feet head develops 214 brake horse power, at 225 revolutions per minute. The maximum discharge of the turbine is 110 cubic feet per second, but at point of best efficiency it discharges approximately 95 cubic feet per second. The design of the turbine is such as to give unusually high efficiency over the complete range of gate from half to full opening.

It is stated that during certain seasons of the year the water used by these plants contains a considerable amount of fine sharp silt, which is very destructive to the submerged wearing parts of the turbine and pumps, and this condition was given special consideration in the design of the machinery, and suitable provision made for protecting the parts against wear, and also for renewing with minimum expense and inconvenience such parts as could not be sufficiently protected. This design incorporated the use of a cast-iron ring or guide ring, which was embedded in the concrete scroll. This speed ring has stationary guide vanes which direct the water in towards the turbine runner. This speed ring was made very heavy and strong, and on account of the slow velocity of the water its action would be in no way detrimental to same. Inside this speed ring are placed the top and bottom plates, between which the wicket gates of the turbine are located. These top and bottom plates are provided with removable steel wearing plates which can be easily renewed.

It is of interest to note that the wicket gates are of cast steel, and the gate stems or spindles are cast integral with the wickets, and the gate spindles move in bronze bushed bearings in the top and bottom plates. The gate stems on the upper end extend through stuffing boxes in the top plate, and all the gate mechanism is located on the top plate where it is in plain view of the operator for the purpose of inspection and lubrication. This design leaves practically no movable part of the turbine in the water except the cast steel wickets, and the turbine runner. There is no step bearing in connection with the turbine unit as it is of the suspended type and the weight of the rotating element, including the turbine runner, the turbine shaft, and the downward thrust of the turbine, as well as the rotating parts of the pump unit are supported by means of an oil bath thrust bearing



WATER TURBINE USED TO PUMP WATER

placed on top of the pump unit, the turbine and pump being so designed as to support this bearing and the load which it carries.

It is pointed out that the top plate of the turbine is cored and the water drained from between the runner and the top plate down through the guide vanes of the speed ring, these guide vanes being cored out for that purpose, which is a design patented by the builders of the turbine. The speed ring and the extension ring above it (known as the pit liner) are so designed as to support the pump unit. The gate operating mechanism of the turbine consists of hand wheel and worm gearing so arranged that the turbine gates can only be moved very slowly, thus giving fine adjustment and avoiding water hammer due to the long discharge line.

As the photograph shows clearly, the pump is of the vertical shaft, four-stage type, with 20-inch diameter intake and discharge openings, having a capacity of 7,500 gallons per minute against 78 feet total head, and requires approximately 212 h.p. maximum. The general design and construction of the four-stage pump consists of four individual cases substantially bolted together, and extends about 16 feet above the floor. The intake connection is made at the bottom, and the discharge at the top of the pump. The three initial or lower stages contain suitable guide vanes, which guide the water in a continuous stream through the pump. These guide vanes form a part of the pump casting. The upper stage or discharge case of the pump is of spiral or volute form, increasing to 20 in. diameter where it connects to the discharge line, an outside screw rising stem 20 in. gate valve being located between the discharge flange of the pump and the pipe line.

There are steel wearing rings around the suction inlets of the pump impellers, also wearing rings in the pump proper provided for the purpose of insuring easy and inexpensive renewal of such parts as are affected by the silt in the water.

It is stated that "reliability of operation without attention except for short periods daily" is the manner in which the Government engineers specified the type of unit to meet the requirements of this plant, and the equipment furnished is as nearly "fool proof" as it is possible to design and build. The hydraulic turbine and accessories, together with designs of the concrete scroll and concrete draft tube, are of the S. Morgan Smith types, developed at York, Pa., while the Byron Jackson Iron Works type was developed at San Francisco, Cal.

It is held that a similar combined unit is to be used for installation at the Price Stub Pumping Plant of the Grand Valley Project of U.S. Reclamation Service in Colorado, where the net head on the turbine is 17 feet and the water is supplied to the turbine through a 60-inch diameter penstock, 150 feet long. The turbine will be a 25½ in. type "O," developing 125 h.p. at 240 revolutions per minute, and maximum water for power purposes being 77 cubic feet per second, and the normal 70 cubic feet per second.

It is said that the pump will operate against a total head of 31 feet including friction, and deliver 13,000 gallons of water per minute through 350 feet of 36 in. diameter discharge pipe. The pump will have 24 in. diameter inlet and discharge openings. This plant will be located on the Government High Line Canal, approximately two miles from the town of Palisades, Colorado, on the Denver and Rio Grande Railroad. These units are the latest and most efficient devices, and great extensions are expected in this service in the near future.

The Control of Large Amounts of Power---III.

The Author, in a Paper Read Before the Institute of Electrical Engineers, England, Gave Some Interesting Remarks Regarding Control of Large Amounts of Power and the Use of Reactances

By E. B. WEDMIERE

Current-limiting By the Use of Busbar Reactance

THE question is, how far in the system generally can the short-circuit current be controlled by the use of busbar reactance in the generating station.

The value of the short-circuit depends upon five availables:—

(a) The working voltage.
(b) The total generator capacity.
(c) The generator reactance whether internal or external.
(d) The busbar reactance.
(e) The number of busbar sections.

The results obtainable may be reduced to a single diagram, using the short-circuit current obtainable without busbar reactance as a unit. This is readily ascertainable as follows:—

$$\text{Short-circuit k.v.a.} = \frac{\text{Total generator k.v.a.} \times 100}{\text{Percentage generator reactance}}$$

Taking this as the unit, Figs. 6 and 14 show the reduction obtained with different values of busbar reactance "B" expressed in terms of the generator reactance "A" and for different number of busbar sections.

Fig. 6 represents the star design and Fig. 14 the closed ring design. In the latter, current is fed from both sides so that reactances are required of about twice the ohm value for the same degree of protection. In Fig. 14, therefore, the vertical scale has been doubled, and with this alteration it will be seen that the two sets of curves are very similar.

In Fig. 6 from the bottom of the diagram it is evident that the introduction of a small amount of busbar reactance has a big effect in reducing the short-circuit values. As the reactance value is increased its effectiveness by no means increases proportionally. The same is true of increasing the number of sections. The curves are figured from the following formula, giving the factor f, that is, the ratio between maximum short-circuit currents with and without reactance:—

$$f = \frac{(N-1)+\left(\frac{B}{A}\right)}{N\left(\frac{B}{A}+N+1\right)}$$

where A = generator reactance,
B = busbar reactance,
N = number of sections.

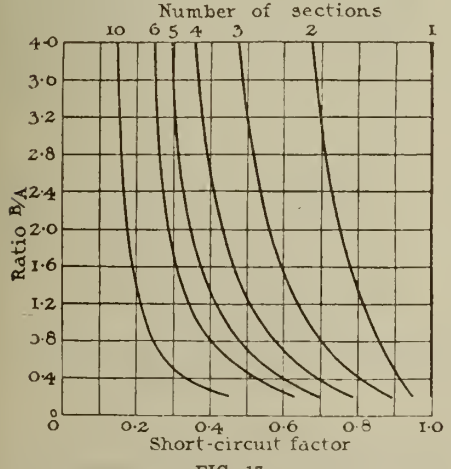


FIG. 17

The results are shown in a different form in Fig. 15, in which the horizontal ordinates are the inverse of those in Fig. 6. It will be noticed that the factor f has equal increments for each additional busbar section.

These curves are based on the assumption that the bull complement of generators is connected to each busbar section, whereas the worst case in practice is shown in Fig. 16. Separate curves would be required for each case there shown. The above curves give results a little on the high side if the total generator capacity is taken as a basis, and on the low side if the maximum of machines running on maximum output is taken as a basis.

These curves cover the ground of what is practicable, as it will be shown later that the amount of busbar reactance permissible is limited by the permissible voltage difference between busbar sections, and that in the endeavor to keep down short-circuit stresses the increase of generator reactance will keep down the ratio well within the range of the above curves and within economical limits. These are the factors which will be found to determine the cost, but a few words may be said here on the question of the best value of the ratio B A from the cost aspect.

We have to consider the total protective value obtained with generator plus busbar reactance, and this is indicated in Fig. 17, in which the vertical scale gives the number of times the short-circuit current exceeds the normal output of the machines. It should be noted that these curves are figured on the total plant capacity and not on the maximum output of the plant. They show the ratio for two and for five sections and with different values of busbar reactance.

Based on these, Figs. 18 and 19 have been prepared showing different combinations of generator and busbar reactance giving equal protection.

So long as the generator reactance can be provided internally the cheapest combination will be that with minimum busbar reactance, but even if all necessary protection of plant could be obtained with generator reactance alone it would still pay to employ busbar reactance owing to the protection afforded to continuity of supply.

In case some of the reactance is put external to the generators there will be a value of B A giving minimum cost. This ratio can be varied over wide limits without materially affecting the cost, and the best figure depends upon how much reactance is external and upon the number of busbar sections and transfer capacity required. As a rough guide it may be said that for five busbar sections the minimum is reached when B/A is in the neighborhood of unity, and with two sections when B is 1/3 A, but either ratio may be varied by 2 or even 3 to 1 without seriously affecting costs, so here again we have to look to technical grounds for our limiting features.

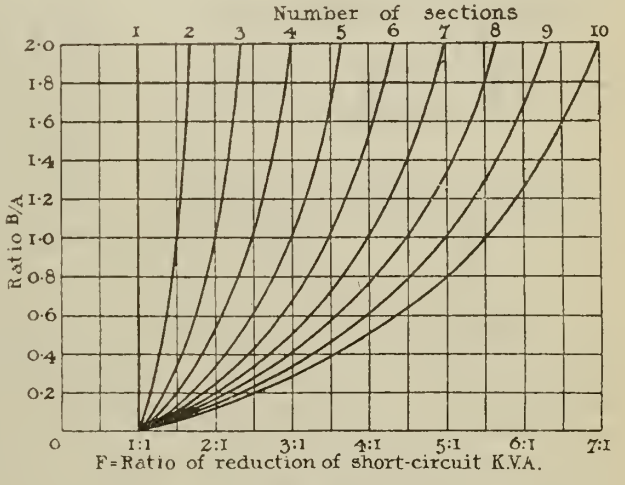

FIG. 18

Transfer of Load Through Reactances

The conditions requiring the largest load transfer with different numbers of machines per section are illustrated by Fig. 16. The relation between the generator capacity tied to a section and the maximum load on that section is scheduled below on the basis of machines of uniform size and of two spares. In practice one has to deal with unequal sections and machine capacities, but one aims at equal sections and generator capacity per section, two small machines counting as one large one. The spares of largest size are the principal determining factor, so that the conclusions drawn give a good idea of what is re-

quired and indicate the basis on which individual cases should be worked out.

Referring to Fig. 16, the diagram for two machines per section is typical. In this, the worst case occurs when the station is fully loaded, i.e., all but the two spare machines are running, and the two machines shut down are on the same section. The section is tied solidly to the adjacent section, forming one section with two machines directly connected, this being the permissible maximum. One reactance is also cut out, so that the doubled section is properly protected by a single reactance.

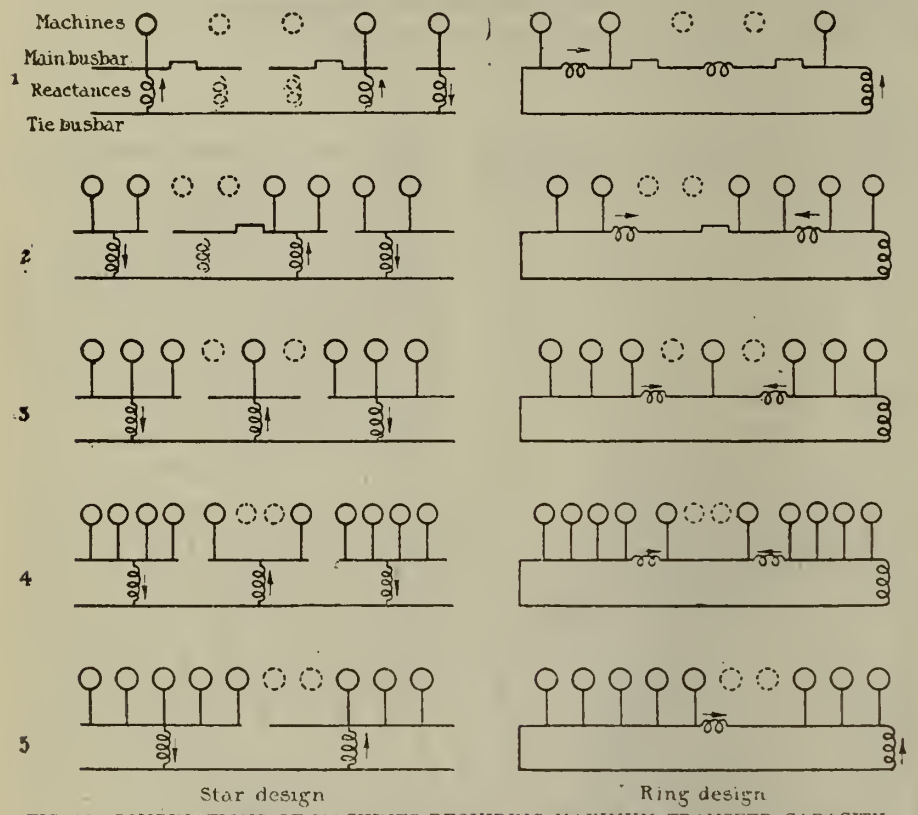

FIG. 16—COMBINATIONS OF MACHINES REQUIRING MAXIMUM TRANSFER CAPACITY

The conditions shown in the figure will arise not only out of necessity, but also out of convenience in the normal operation of the plant, and should be met by the provision of ample carrying capacity in the reactance, rather than by special switching operations involving the use of the auxiliary busbar.

Schedule A gives the transfer capacity for the star design for each of the cases illustrated. On referring to Fig. 16, and to the diagram for the ring design, it will be seen that the transfer capacity in the first figure must be the same for both ring and star design. In the remaining cases in the ring design the transferred load is divided between two reactances which so long as the ring is closed could, therefore, have half the current capacity. On the other hand if the ring is broken, as it is bound to be from time to time, then in the worst case one reactance must carry the total transfer as in the star design. This worst case is most likely to happen if there are only two busbar sections, and will happen in the other cases if we have two machines on one section down and need to shut down an adjacent busbar at full load, a rather unlikely contingency. If this case arises and is not provided for, then we shall be compelled temporarily to cut out reactance or operate with excessive potential difference.

With the ring design a compromise can be effected by allowing, say, three-quarters of the capacity shown for the star design.

A study of Fig. 20 will bring out the meaning of the data scheduled.

It will be noted that for a given total output and number of machines per section, the transfer capacity required does not vary much with the number of sections. The falling-off would be compensated if with the larger number of machines more than two spares were provided. It should also be borne in mind that the figures are based on one size of machine throughout, whereas on some sections, and especially the first installed, there will be an equivalent capacity made up of smaller machines. These require less transfer, so that in actual conditions the capacity required is practically determined by the final total output aimed at, and must be made sufficient for this.

For a given amount of protection and number of sections, the number and ohmic value of the reactances are fixed, so the cost varies only with the transfer capacity. These curves, therefore, give a good idea of the relative cost of different numbers of machines per section. It will be seen that one machine per section gives the lowest cost, but in some cases with an impracticable number of sections.

Further calculation shows that the cost of the reactances for a given measure of protection decreases with an increase in the number of sections, but on the other hand the cost of the necessary switchgear for the larger number of reactances is increased, and investigation of two typical cases indicates that the balance is negligible.

It is clear, therefore, that in considering the best number of sections to employ the question of cost of the reactance equipment is not a guiding feature.

Fig. 21 gives the results in a convenient alternative form.

Transfer of load through busbar reactances at high power factor. — When energy is transferred from one busbar section to another at a power factor higher than that of the load, the shortage of magnetizing current has to be made good by the machines connected to the section receiving energy. These machines will then be operating at a reduced power factor and consequently with a reduced energy output. Fig. 22 shows the relation between rated output and power factor typical of modern machines, and it will be seen that if the machine is rated at 100 per cent. k.v.a. at 80 per cent. power factor, then the k.v.a. output is reduced ultimately to about 80 per cent. at zero power factor.

Fig. 23 shows the voltage difference required for the transfer of load at 80 per cent. power factor through reactance between busbars, the reactance in this case being the effective reactance of any combination of units there may be in

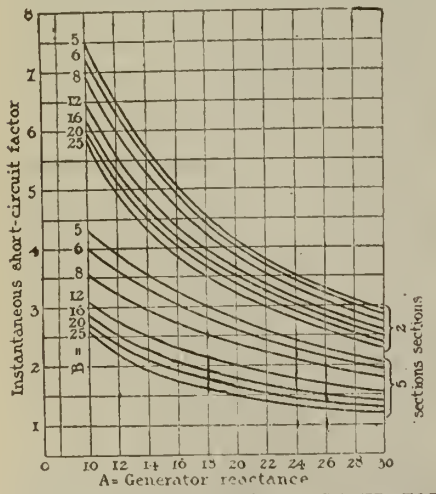

FIG. 17—COMBINED EFFECT OF GENERATOR AND BUSBAR REACTANCES, STAR DESIGN WITH TWO AND FIVE SECTIONS.

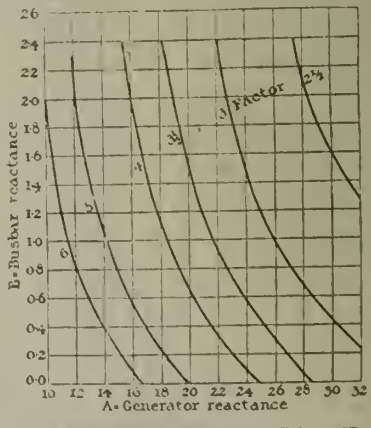

FIG. 18—COMBINATIONS OF "B" AND "A" GIVING EQUAL PROTECTION, STAR DESIGN WITH TWO SECTIONS.

series and parallel between the sections in question.

Fig. 24 shows the advantage of furnishing magnetizing current from the machines running in the section to which energy is being transferred. The load is

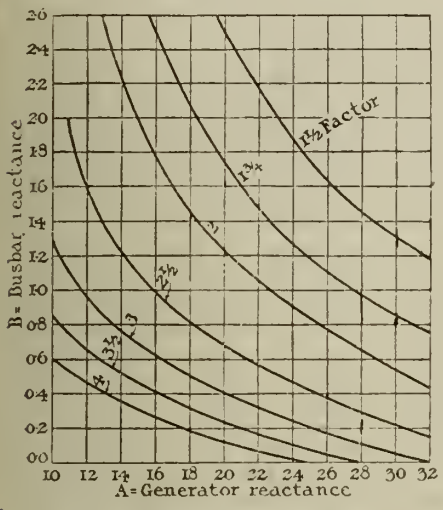

FIG. 19—COMBINATIONS OF BAND "A" GIVING EQUAL PROTECTION, STAR DESIGN WITH FIVE SECTIONS.

again taken at 80 p.c. power factor. The lower curve requires transfer of load at 80 per cent. power factor. With the top curve the whole current output of the machines running on the section is taken as magnetizing current. It will be seen in this case that with half the machines running, if the section output is to be three-quarters of the section capacity (i.e., allowing 25 per cent. spare plant), one is limited to 11 per cent. equivalent reactance between machines, but this rapidly increases up to a theoretical limiting figure of 30 per cent. as the power factor of the running machines is decreased.

These curves are drawn for a potential difference of 1¾ per cent., this figure being the drop due to the reactance. There will be a small additional drop due principally to the energy component of the load causing I R drop. This will be in general less than ¼ per cent., so that the figures of 1¾ and 2¼ per cent. chosen correspond to a maximum difference of about 2 and 2½ volts, or a variation from normal of 1 and 1¼ per cent. in volts.

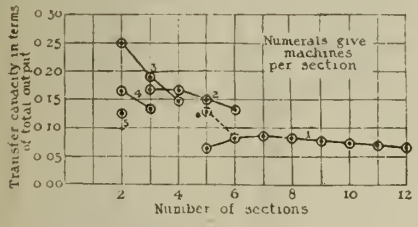

FIG. 20—TRANSFER CAPACITY OF REACTANCES (STAR DESIGN).

We can now determine the maximum value of busbar reactances for different conditions of running. These are set forth in Schedule B. This Schedule is prepared to cover different numbers of machines per section and of sections, and covers a very wide range, because it will be found that with a given number of machines per section, the number of sections does not exercise much effect; for in the first place one has to allow from the commencement the transfer capacity that will be necessary in the complete installation, and in the second place it will be found that if each likely combination of machines and sections is worked out in detail the maximum values of B do not vary much with the number of sections.

The third line shows the maximum load transfer required at full load in the most unfavorable case as shown in Fig. 16, and the next line shows the maximum value of B for 2½ per cent. voltage difference, the load being transferred at 80 per cent. power factor.

If we meet this extreme case by adjustment of the machine power factor we get at once a big increase in the possible amount of reactance, and with a voltage variation of 1 per cent. from normal we can get the results shown in line 5.

Generally at full load on any one section we can arrange to have not more than one machine shut down on that section, and can thus transfer at 80 per cent. power factor through much larger reactances. The figures are given in line 7.

For investigation of the limiting effect on short-circuits the author has assumed

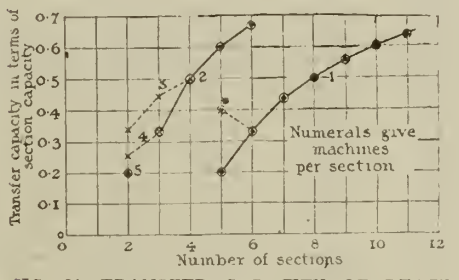

FIG. 21—TRANSFER CAPACITY OF REACTANCES (STAR DESIGN).

this to be the normal condition of operation, and that adjustment of power factor will be resorted to only in the extreme case and then will be limited to 50 per cent. power factor. We then get the permissible maximum B by combining lines 5 and 7. The result is shown in line 8 and does not necessitate approaching the 50 per cent. power factor limit except where there are 3 or 4 unit machines per section.

Based on these figures for B, the short-circuit factors are figured and shown in Schedule C. This factor is the figure by which the rated capacity or output, as the case may be, must be multiplied to get the maximum instantaneous output on short-circuit.

Heating and Stresses Due to Heavy Currents

We have now considered how the concentration of power on a fault occurring can be limited. We have yet to consider the heating and stresses due to the large currents still to be dealt with, both under normal and under faulty conditions.

Electromagnetic Stresses on Conductors.—In modern practice conductors in different phases may be spaced at 1-inch centres or less as in cables, or at 2-ft. centres or more as in large switchboards.

With adjacent conductors at 12-inch centres carrying currents in opposite directions, the maximum repulsive force between them will be 9 lb. per foot run for 10,000 amperes, R.M.S. value. The

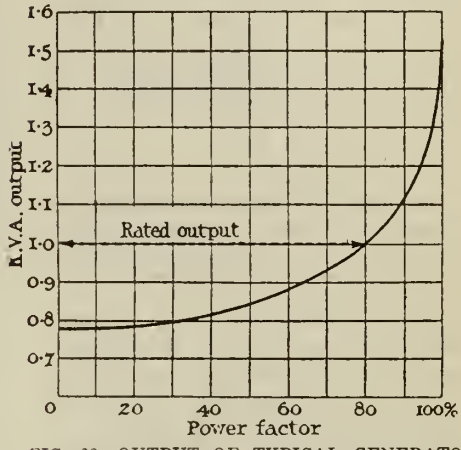

FIG. 22—OUTPUT OF TYPICAL GENERATOR AT DIFFERENT POWER FACTORS.

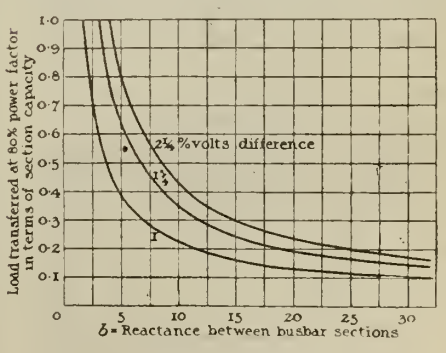
force varies inversely as the distance and proportionally to the square of the current, and often attains serious proportions in modern practice.

In a three-phase cable carrying 100,000 amperes on a fault the force may reach a maximum of 12,000 lb. per foot run, and would approach this in the joint boxes.

Conductors spaced 1 foot apart will be subjected to 900 lb. per foot run on the same current. If the conductors are securely fixed at the ends, the stress on the end supports may be many times this. It becomes essential to support the bars in such a way as to prevent these forces from causing destruction.

A current of 100,000 amperes may be met with on the direct-current side of large rotary converters and on the low-tension side of large power transformers, as well as on the high-tension circuits in very large power stations.

In current transformers designed with multiple-turn primary windings and with coils lying side by side, large forces are



Load transferred at 80% power factor in terms of section capacity
2½% volts difference
1¼
1
δ = Reactance between busbar sections

FIG. 23—VOLTAGE DIFFERENCE DUE TO TRANSFER OF LOAD.

produced on short-circuit, tending to drive the coils apart and distort the ends if unsupported.

With typical modern designs the safe limit is reached when the currents are of the same order of magnitude as indicated below also for heating limits. The

transformer should not be subjected to more than 200 times normal load current.

Where a conductor forms a loop there is a force tending to expand the loop, the magnitude of which is given by the following formulae:—

In Fig. 25 (a), $F = \frac{9C^2}{D}\left(\log_e \frac{4D}{d} + 0{\cdot}1\right) \times 10^{-8}$

In Fig. 25 (b), $F = \frac{9C^2}{D}\left(\log_e \frac{2D}{d}\right) 10^{-8}$

where F = lb. per inch,
D = inches,
C = amperes.

These cases are illustrated by Fig. 25, and, based on the figures they give, a fair estimate may be made of most cases which arise in practice.

A 300-ampere isolating switch of the type shown in Fig. 26, or an oil switch of the type shown in Fig. 27 with insulators at 10-in. centres, may have a force of 100 lb. distributed over the blade on a current of 20,000 amperes, or 600 lb. for 50,000 amperes. If the switch be designed as in Fig. 28, the conductors will be almost in line with the blade, and the force due to the loop formation will be relatively negligible.

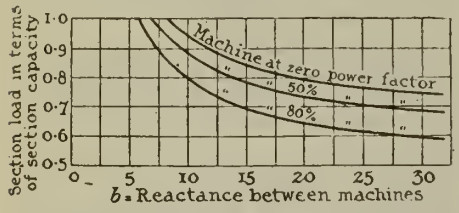


FIG. 24—INFLUENCE OF POWER FACTOR OF MACHINE ON OUTPUT OF SECTION. LOAD AT 80 PER CENT. POWER FACTOR.

It is good practice to lock or latch the blades of all back-connected isolating switches on 6,000-volt plants where the output may reach 10,000 k.v.a. or upwards, and to latch all switches where the output may exceed 20,000 k.v.a. These figures are typical of what is required.

The forces acting on the conductor carrying current in the arc in a direct-current circuit-breaker with 6-in. break may be roughly estimated. When the carbons separate, the force of 10,000 amperes may be of the order of 3 lb. per inch, and when a loop of 3-in. radius is reached the force will be again something like 3 lb. per inch run.

Design of large conductors.—Up to about 2,000 amperes' capacity the design of conductors for alternating-current

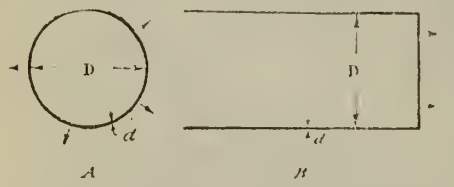

FIG. 25—DIAGRAMS SHOWING FORCE IN CONDUCTORS CARRYING CURRENT.

circuits presents no peculiarity except in machines and transformers where eddy currents may be set up in them, but above this figure "skin effect" has to be seriously considered. The skin effect in circular conductors admits of simple mathematical treatment. The figures for conductors of square cross-section can be calculated approximately from the solution for cylindrical conductors. The case of a very wide strip conductor also admits of easy solution, and by interpolation between these results one can

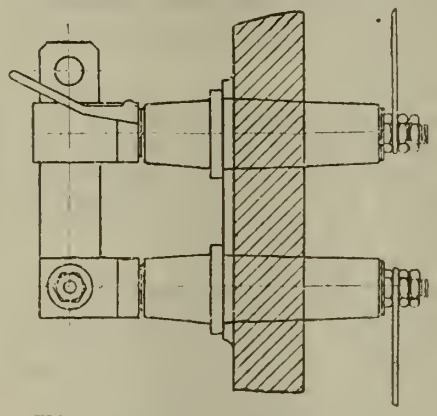

FIG. 26—TYPICAL ISOLATING SWITCH, SUBJECT TO LARGE FORCES.

arrive at a fair idea of what happens in rectangular conductors as usually employed for busbars and heavy conductors, in the form of laminated bars with ventilating ducts between the laminations.

As to the thickness of lamination ¼-inch is a common and convenient dimension with ¼-inch ducts. With vertical conductors the ducts should be increased where practicable to ¾ inch. There is no benefit in building up alternating-current conductors of bars ⅜ inch thick.

So long as the total thickness of the copper in the several laminations added together does not exceed 1¼ inches, skin effect does not become serious, but above this figure it rapidly becomes a most important factor.

Additional capacity can only be got by increasing the width of the bars in some way, or alternatively by so arranging them that the inner and outer conductors are changed over so that each current stream flows through roughly equal lengths of inner and outer conductor. The bar should then be constructed of an even number of laminations, suitably separated by light insulation and space provided for by the cross-over connection, which is not a very simple affair.

Where currents of the order of 5,000 amperes or upwards have to be or may have to be dealt with, it is, therefore, essential to provide ample room for the maximum width of strip which may be ultimately necessary and to keep down the maximum current to be dealt with, as, for example, by interleaving heavy incoming and outgoing circuits as in Fig. 8.

Stresses Due to Heating of Conductors—If a copper conductor is prevented from expanding and is then heated, it will exert a stress of about 240 lb. per square inch for each degree Centigrade rise of temperature. If the supports spring sufficiently to admit of expansion taking place, the stress will be limited to the amount necessary to spring the supports.

A copper busbar 10 ft. long and 2 sq. in. cross-section, able to carry, say, 2,000 amperes, will thus exert a theoretical maximum pressure of about 15 tons for a total temperature change, due to electric heating and atmospheric conditions, of 60 degrees C. This same bar for the same temperature change will increase in length by about ⅛ inch. This can be absorbed by deflecting the bar about an inch at the centre if it is free to move, or by the slipping of the bar on its supports. Expansion is generally taken care of by slipping. It is, however, good practice on long busbars to limit this by the use of expansion joints.

Heating Effects of Large Currents

With the increase in the size of plant we reach limiting conditions due to heating effects, as we have on emergency conditions very high current densities to contend with. The heating effect being proportional to the source of the current quickly reaches abnormal figures. A plant may be quite safe against heating troubles and have perhaps a factor of safety of 4, but on doubling that plant the margin disappears.

If heat is generated in a conductor very rapidly there is no time for radiation, convection, and conduction to play their part, and the heat is practically wholly absorbed in the conductor, resulting in a corresponding temperature rise Currents flowing in copper conductors 1,000 amperes per square inch will raise the temperature 50 degrees C. per hour if the heat is all absorbed. On this basis a current of 100,000 amperes, say 1,000,000 k.v.a. on 6,000 volts, will raise the temperature of a 0.1 sq. in. cable at the initial rate of about 12,500 degrees C. per second.

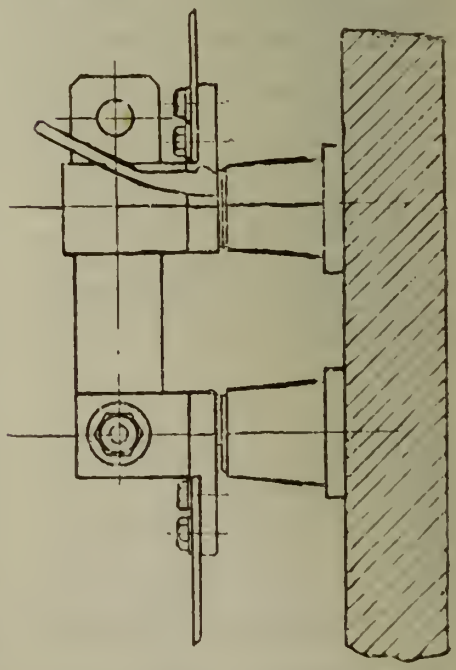

FIG. 28—TYPICAL ISOLATING SWITCH SUBJECT TO SMALL FORCES.

Under conditions which are permissible, the insulation on conductors does in fact absorb a considerable amount of heat and the theoretical maximum temperatures are not reached. For coils

wound with wire or thin strip the rise may not be more than half the theoretical figure. On average underground cables the discrepancy would be something more like 10 per cent. Using this latter margin we get the following round figures for temperature rises:—

Density	Rate of Temperate Rise
10,000 per sq. in.	1¼ degrees C. per second
100,000 per sq. in.	125 degrees C. per second
200,000 per sq. in.	500 degrees C. per second

The effect of these figures in practice will be seen by an examination of the round figures in the following table, giving the maximum permissible k.v.a. in a circuit for a current density limited to 100,000 or 125 degrees C. rise per second.

Cable.	Maximum Current.	k.v.a. at 6,000 Volts.	k.v.a. at 20,000 Volts.	k.v.a. at 30,000 Volts.
Sq. in.	Amp.			
0.025	2,500	25,000	85,000	125,000
0.050	5,000	50,000	175,000	250,000
0.100	10,000	100,000	350,000	500,000
0.250	25,000	250,000	850,000	1,300,000
0.500	50,000	500,000	1,750,000	2,600,000

The current values are R.M.S. values and the k.v.a. is figured three-phase.

The above figures give the initial temperature rise. The effect of the initial rise is, however, to raise the resistance of the copper conductors, the specific heat remaining steady so that the rate of rise is accelerated as it proceeds.

The serious overheating of a conductor in a cable may damage the cable from end to end.

Experience with stations designed in recent years and having a maximum short-circuit current of 10 times their normal rated output, has shown that it is necessary that the smallest current transformer on the main switchboard should have a carrying capacity not less than one-twentieth the station output. Current transformers of good design and much smaller than this have been known to be exploded by the heat generated on a short-circuit.

On one plant already existing in this country it has been found desirable to limit the cross-section of the smallest conductor to 0.15 square inch. The figures given above show clearly that in the large plants now in contemplation this feature will require careful consideration.

Everybody Pleased

That Power House Will be Issued Semi-monthly

"POWER HOUSE is certainly a book well worth looking forward to and I will look forward to the semi-monthly edition with great pleasure. As regards the subscription price, I think it should be increased according to the upkeep of the paper."—Mr. Wm. R. Symons, Toronto.

"Referring to the issuing of POWER HOUSE semi-monthly. I am delighted to hear this as I am always looking forward for my next issue before the half of the month is past and it is awful to have to wait all that time for it. If I had my way I would have it every week, and right here I will state that whether it is to be issued weekly, monthly or semi-monthly, I will still be a subscriber."—Mr. R. S. Wright, Sudbury, Ont.

"In reference to changing POWER HOUSE into a semi-monthly. Readers will be delighted. We all know that it is difficult to get too much of a good thing. I hope seeing POWER HOUSE a weekly some day. I have taken it from the first issue and say with truth that I have received pleasure and profit from every copy."—Mr. James E. Noble, Engineer, c/o Rockwood Hospital, Kingston.

"Two editions each month! I am sure that will be excellent, it is so interesting. I often think it is long in coming. I am sure if you keep the POWER HOUSE up to the interesting standard you have it at present, two dollars a year will not be too much."—Mr. Alex Angus, St. Pierre, Que.

"I think semi-monthly POWER HOUSE a capital idea. It certainly will be appreciated by me and I think by all Power House workers."—Mr. J. D. Blair, Victoria, B.C.

—and there are a stack of other letters brim full of good words like these.

—Moral—Subscribe for POWER HOUSE *and get the latest information, through editorials and advertisements, regarding power house plant, equipment, etc., etc.*

An Important Point.—Holding that the attachment of a piece of machinery securely to the wall of a building did not make that machinery a permanent part of the building and as such an "immovable" under the law; that an indispensable condition to thus changing a piece of machinery from a "movable" to an "immovable" was that the machinery and the building should at one and the same time be the property of the individual making the change, Mr. Justice Mercier in the Superior Court at Montreal, maintained a seizure made by the Matthew Moody & Sons Company, upon certain machinery and effects in Francois Xavier's mill at St. Anicet, Huntingdon County, and ordered the defendant Dupuis to return the machinery to plaintiffs or pay its value.

Grading Coal For the Small Consumer

THE proper utilization of coal in many cases depends upon the getting of satisfactory coal in the first place. The suggestion received from a correspondent and which we print on another page deserves considerable attention as tending to eliminate the practice, on the part of the dealers, of selling to the small consumer coal of inferior quality. The power plant owner who has no facilities for testing and who does not buy sufficient coal to warrant purchase by specification would benefit greatly by the proper grading of coal and the householder, needless to say, would derive equal advantage to the elimination of much slate, clinkers and bad temper.

War conditions in many cases were seized upon by operators as a golden opportunity to unload upon the public and the power plant owner, coal of a greatly inferior quality and the disappearance of the culm heaps at the pit mouth give evidence to the amount of inferior coal sold. This condition, no doubt, is to some extent excusable under war conditions, but with the coming of peace and the return to normal industrial conditions more rigorous control of the quality of coal supplied would not only be welcome but would seem quite feasible.

Selling Alberta's Coal Output

THE coal operators of Alberta are having troubles all their own seeking to place their product in successful competition with the American coal in the Winnipeg and Western Canada market. They were quick to make use of the shortage last fall to urge upon Western Canada the advisability of turning to Alberta for their coal supply. They had a big chance to fence off the field, but they find that the element of price also enters into the deal, and in a very pronounced way.

Basing the figures on the returns for the year 1918 it is found that some two million dollars' worth of Pennsylvania coal entered the Western market. The Alberta operators make the point that were this amount spent with them it would enable them to keep their mines going for a greater period than nine months in a year. The longer the mines work, and the greater the amount turned out, it will be seen that tonnage costs come down in proportion.

Be that as it may, the problem for the West right now is how to meet the U.S. producer on a price basis in Winnipeg. Take the two points of production, and trace the costs. Starting at a mine near Pittsburgh the coal costs, including mine labor, overhead charges and loading, are $2.60 per ton.

By the time it reaches Fort Erie, where it is loaded on the boat to be carried up the lakes, it costs $4.32 a ton.

Lake freights, customs duties and various other charges bring the cost at Fort William to $5.51 a ton.

Dock handling charged at Fort William increases the cost at that point to $6.11 a ton.

Freight to Winnipeg brings it to $9.21 a ton.

And the coal dealer who handles it, delivers it, and makes a profit out of it sells it for $12.25 a ton.

That's the story in costs of a ton of Pittsburgh soft coal put into the basement of the owner of a Winnipeg block.

The Alberta coal loaded costs between $5 and $5.25 per ton, and right here the Pennsylvania coal gets an advantage of $2.63 per ton. This is not because the Alberta miners get higher wages, but physical conditions surrounding mining in this country make the costs higher. Taking a ton of coal at the mine, for which the mine owner gets $5, and adding the freight to Winnipeg, the Winnipeg dealer finds it costs him $9.80 or 50 cents more than the Pittsburgh product. And the Winnipeg dealer sells it for $12.75 as against $12.25 for the imported product and makes nine cents a ton less than on handling the imported product, while the consumer pays 50 cents more.

Alberta has a definite job ahead of it now if it wants to fence off Western Canada as its biggest and best customer for coal. That definite job consists of wearing off that fifty cents per ton difference that now rests in favor of the U.S. producer of coal. A little more efficiency in mining and handling might go a long way toward accomplishing this end, while the freight charges might be made the subject of a very close inquiry. Flattening out this fifty cents per ton in playing for a two million dollar order looks like a worth-while proposition.

Association and Personal

John A. Greig, of Ross and Greig, has been elected president of the Caledonian Society of Montreal.

The death occurred, on Monday, March 24, of R. A. Hogge, purchasing agent for the past few years for the Steel Company of Canada in Montreal. Mr. Hogge was born in Dumfries, Scotland, in 1886, coming to Canada in 1910. After a period of service with Messrs. Hugh Russell and Sons, iron and steel merchants, he entered the employ of the Steel Co. of Canada in 1912 as clerk in the works office, subsequently being promoted to purchasing agent.

The death of George W. Cole occurred at his late residence, 64 Parkway Ave., Toronto, from heart failure. Mr. Cole was born in Norwich, Ont., and was in his fifty-ninth year. He came to Toronto about seven years ago and organized the business known as George W. Cole, Limited, 2002 Dundas St. West, of which he was president and general manager at the time of his death. Private services were held at his late residence, after which the body was taken to Norwich. Mr. Cole leaves a widow, one daughter, Margaret M., and two sons, Brock L and Grant E.

Contemplated Expansion. — Peacock Bros., of Montreal, who for many years have been Canadian agents for G. and J. Weir, Limited, of Glasgow, are now manufacturing the Weir feed pumps in their own factory recently established in Montreal. Considerable new equipment has been obtained from the States and England, and the new plant is amply equipped to handle efficiently this new branch of their operations. It is announced by officials of Peacock Bros. that the Clyde Engineering Works are contemplating increased expansion of their business in Canada.

Briquetting of Coal.—At a recent meeting of the Montreal branch of the Engineering Institute of Canada, a paper was read by Paul A. Seurot, M.E.I.C. on "Coal Briquetting," in which he emphasized the importance of developing this industry for the purpose of materially assisting in the solution of the ever-present fuel problem, and at the same time aid in making Canada more independent in this regard. He stated that of the total coal brought out of the mines, from 10 to 35 per cent. was practically wasted, and if proper facilities were provided the bulk of this could be economically utilized. Some little attention was given to this matter out West where some 1,100 tons of coal was briquetted per day, but when compared to other countries, Canada was far behind in the development of this industry.

CHANGES ANNOUNCED

The Canadian Ingersoll-Rand Company, Limited. has recently absorbed the Jenckes Machine Company, Limited of Sherbrooke, Que., thus putting them in possession of two plants, the "Jenckes plant," and the "Rand plant." The products of the "Jenckes plant" will continue to be those familiar to customers of the Jenckes Machine Company, manufactured to the latest designs. Briefly, these are: structural and plate work; tanks, penstocks, etc., mining machinery and equipment, ore crushers, cars, cages, etc., and pulp and paper equipment such as barkers, grinders, water wheels, etc. The headquarters of the Canadian Ingersoll-Rand Company are at 260 St. James St., Montreal.

Jobs For Them.—One thousand jobs are awaiting Detroit's returned crippled soldiers at Ford Motor Company's plant in Highland Park. This announcement was made by Edsel B. Ford, president of the company. The men will be paid the minimum wage of six dollars a day of eight hours now in effect in the plant. "The thousand soldiers are wanted for our new self-starter department," said Mr. Ford. "The only requirements necessary are that they are crippled soldiers, Detroit men, and have use of their hands. Men who have lost both legs and an arm will find work with us that they can do. We can use these men whether they have to stand up or lie down at their work."

A METHOD FOR THE PROTECTION OF THE PURCHASER OF COAL IN SMALL LOTS

The Editor.—

IN the matter of purchasing coal, large corporations protect themselves by buying under rigid specification as to calorific value, ash content, etc., but for the small consumer, whether buying merely for household needs, or for a small industrial plant, there is no protection whatever.

It has occurred to me that it might be possible to institute some system of Government control, whereby the supplies obtained by dealers could be sampled and properly tested by an expert in the employ of the Government, who would grade the coal according to its value as a fuel, arranged, for example, into classes A, B, C, D, etc., and the coal could then be sold on a grade basis.

It is not proposed here that the Government should exercise any control over actual prices charged, but merely that matters should be so arranged as to prohibit a dealer from selling, say, a grade "D" coal at a grade "A" price, thus instituting at least some measure of protection in the interests of the small consumer.

I am fully aware that the working out of this suggestion is not so simple as it looks, but cannot persuade myself that the difficulties are insurmountable.

Even if the ideas proposed above should prove to be impracticable for some reason or other, I think it should be quite feasible for one of the Provincial Government departments to arrange a system, whereby, should a consumer feel dissatisfied with his purchase of coal, he should be able to arrange for a sample to be taken from his coal bin by a Government expert for test, and, if it be found that his grievance is a real one, there should be machinery established, by means of which he could obtain some redress.

At the present time, if any one wishes to have a sample of water tested, it is a simple matter to have this done by sending it to the Parliament Buildings, where an analysis is made. There seems to be no good reason why similar facilities could not be afforded to the public in connection with coal. The sampling would no doubt be a little more awkward, as it would be necessary for an expert to undertake this, since the ordinary householder, or even the owner of a small industrial plant, assuming him to be honest enough to do his best, could not be expected to obtain from his bin a really representative sample.

There are, of course, various details in connection with either of the foregoing suggestions, which would have to be worked out in order to establish a thoroughly practicable scheme, but I think that for a start, some general discussion of the main ideas would be profitable.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

Readers are invited to send in answers to these problems, as they have been chosen for their interest and application to the practical side of power plant operation.

Perhaps you, too, have some pet problems, or hard nuts which you would like to ask your fellow engineers; if so, send them along for the benefit of others.

Answers, together with the original question, will be published in the issues following the appearance of the question.

Questions Before the House

1. A horizontal return tubular boiler, 72 in. dia. by 18 feet long, made in three courses, has sustained damage by the plate over the fire becoming overheated. The plate has come down in a blister of elliptical form, the axes being 14 in. in a longitudinal direction, and 36 in. in a circumferential.

How would you put a single riveted patch on this boiler so as to preserve the full strength of the longitudinal seam? Would you put the patch inside or outside the plate?

2. In the case of a pump having a lift of over twenty-six feet, would the fitting of a foot valve be of any help in starting the pump. Generally speaking, where does the advantage of a foot valve in a suction line lie?

3. Can you state, clearly and definitely, why a longitudinal seam of a boiler requires stronger riveting than the circumferential? Show by figures the relation between the two.

4. The area of a safety valve on a boiler is proportionate to the grate area. What is this proportion, and in what way does the grate area affect the safety valve area?

5. What is the proportionate weight of air to weight of coal used to obtain combustion? Give any formula you know.

6. Can you give a clear description of what takes place when a boiler explodes through failure of a plate. What is the sequence of events?

Readers' Queries

Question.—We have six Scotch boilers working at full capacity. What is the best method to clean fires without letting down steam? Is it possible?

Answer.—This is a question that has been troubling engineers since fires were first lit under a boiler. The ability to clean fires without losing steam is governed by several factors: the condition of the fire, the skill of the man cleaning the fire, and the co-operation of the firemen on the other boilers.

Broadly speaking, there is no better way than the method pursued by firemen at sea, and also ashore, of burning down one half the fire. That is one side of the fire is allowed to burn itself down for perhaps 15 to 20 minutes, while the other side of the fire is fired lightly and evenly, keeping it a good bright fire. When ready for cleaning any unburnt coal on the top of the side to be cleaned is winged over by a slice bar to the side still burning, and the remaining ash, etc., is pulled out as fast as it can be done. When the bars are cleaned the red, fresh coal from the burning side is whisked over onto the clean side, and fresh coal is fired on lightly, and the cleaned side is allowed to burn up before the other side is touched.

In the meantime the other fires are kept in good condition, and worked as hard as they can be. Speed is the essence of the contract, and if the fire door is kept shut, except when actually working at the fire, as much cold air as possible is excluded.

The difficulty arises when a fire is badly clinkered, and the clinker has to be broken to get it through the fire door. Time is inevitably lost, and the man standing up to the hot fire gets played out, so that his activity is seriously curtailed. If now the boilers are being worked hard, and the steam begins to drop, it is going to be some time before it raises again.

Before cleaning a fire, the feed check valve should be shut off, the boiler being cleaned. Intelligent adjustment of the feed checks helps a lot. The boiler being cleaned, has a certain amount of grate surface out of business, and its capacity of evaporating drops. It therefore does not require so much feed, and if the water is a few inches in the glass, the feed can be closed altogether.

If the fire is very dirty, don't attempt to burn down. Pull the whole thing out. You may lose some unburnt coal, but you will lose more by wasting time in trying to burn your fire down, and allowing the steam to drop. The trouble in allowing steam to drop is this:

The steam having less heat energy in it, the engines require a greater weight of steam to perform the same work. The feed water supply has to be augmented to supply this steam. The feed pumps use a greater percentage of the steam produced by reason of the extra number of strokes, and the extra quantity of water passing through the heater lowers the feed water temperature.

Before cleaning, work your water well up in the gauge glasses, so as to have a reserve. Try and arrange to clean only one fire at a time. Clean quickly, and keep the other fires up to their work. You can clean fires without losing steam, but you have to make everyone hustle.

* * *

Question.—We have two banks of transformers, one delta-connected on the low tension side, and the other of a star connected, both primary sides being in delta. Would it be possible to connect these two banks onto the same buses, as the secondary voltages are the same?

Answer.—While at first glance it might appear feasible, any attempt at paralleling the two banks would be disastrous. The voltages due to the two secondaries connected up in these ways are not in phase, but are 30° out of phase with each other, and if paralleled this condition would lead to trouble.

LEAKAGE AT THE BLOWOFF

It often happens that the blowoff valve does not close tightly, either because it is worn or corroded, or because some obstacle has lodged on the seat. In such cases there is a continual flow of hot water out of the boiler, to an extent depending upon the magnitude of the leak; and the heat that escapes in this way is entirely wasted. Leakage of this sort is easily detected by the eye when the pipe discharges directly into the air. When it discharges into a sewer or a blowoff tank, however, some other method must be adopted. The simplest plan is to feel the blowoff pipe from time to time. Leakage can be detected in this way very easily, because the continual escape of hot water, even in small amounts, keeps the pipe abnormally heated, beyond the valve.

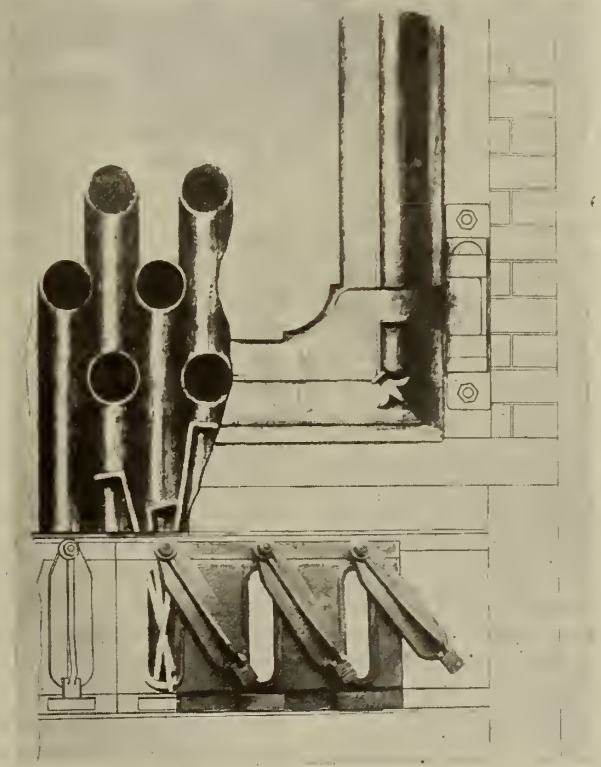
Progress in New Equipment

SOOT-CLEANING EQUIPMENT

IN the average boiler plant equipped with forced draft underfeed stokers burning bituminous coal, or with the Coxe stoker burning small sizes of anthracite or coke breeze, it is usual to operate the boilers at considerably above their rated or nominal capacity.

High ratings are obtained by high air pressure under the grates, the effect of which is to lift small particles of incandescent coke and ash from the grates, which are carried through the boiler in the furnace gases. A certain proportion of this coke or ash adheres to the bottom and sides of the tubes in the bottom row immediately above the fire.

A gradual building up of this cinder occurs slowly, closing the opening between the tubes, so that in the course of a few days or weeks, as the case may be, the area of gas passage is materially reduced, often so much as to reduce the capacity of the boiler.

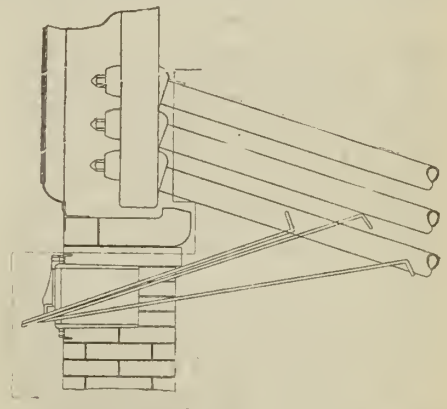


DOORS FOR SOOT CLEANING; FRONT OF WATER-TUBE BOILERS

This cinder can not be dislodged by the usual soot blowers or tube blowers, nor by the older hand lance method, and the only recourse is to cut the boiler out of service and scrape the cinder from the tubes after cooling down the furnace. This is an expensive operation and would be entirely unnecessary if means were provided whereby it would be possible to scrape this cinder off the tubes while the boiler is in service.

The usual tube dusting doors provided in horizontal water tube boiler settings do not give access to the under side of the bottom row of tubes. To meet this condition the Combustion Engineering Corporation, 11 Broadway, New York, offers the C. E. C. tube device, consisting of tube scraping door casting, bottom tnbe scraping doors, scraping tube cleaning or scraping wall boxes and access doors for tube scraping. The device is illustrated herewith. Its purpose is to provide openings in the front or rear wall of a boiler setting, through which a light hook may be used for scraping the cinder from the bottom and sides of the lowest row of boiler tubes.

These boxes are made in sections of 3, 4 and 5 doors which are spaced the same distance apart as the boiler tubes in the boiler in which they are installed. Two or more sections are bolted on angles or a bar along the top and bottom sides, providing one opening or door for each space between tubes. The openings are not in line with the tubes, but are half way between the tubes, so that the sides of the tubes may be reached as well as the bottom, and also the bottom of the second row of tubes.



METHOD OF SCRAPING TUBES

The castings are of sufficient strength to support the brick wall above them and they will, when placed under the rear header of a horizontal water tube boiler of the Heine type, support the weight of the boiler also.

The boxes are about 12 in. deep and heavily ribbed vertically between each door or opening. When installed, the brick work is so laid that the boxes are protected from radiant heat, and being in short sections of 21 to 35 in. in length will not warp and twist and loosen the brick work above and below.

Each opening is covered by a swinging door or cover, also of cast iron, the lower end of which passes behind a tapered spring catch, which can be adjusted by a light blow of a hammer to hold the door tightly against the box.

When cleaning the tubes the attendant takes a rod about ⅝ in. diameter and 10 to 12 feet long, of the same shape as an ordinary fire hook with one prong about 5 in. long. By striking a projecting lug on the door, the door is swung to one side and the hook pushed in the hole. The two tubes immediately in front of the opening are then scraped with one or two passes of the hook along the sides and bottoms, the hook withdrawn and the door closed by striking the door lug with the hook. In this manner the lower tubes may be cleaned once a day or once in two days, or more, as may be required.

This device is inexpensive and costs little to instal.

Every time a boiler is cut out and cooled down it is necessary to burn a certain amount of coal to merely heat the boiler brickwork up to the normal operating temperature. This amount is variously estimated at from 650 to 1,200 lbs.

If the cinder is allowed to accumulate on lower tubes, the capacity may be reduced to the rated horsepower of boiler in two weeks' time and the economy will fail, particularly if the plant is designed for maximum economy at a certain overload. The sum of the economies that may be maintained by the use of this device is a considerable one, and while it is difficult to give exact figures it is not hard to show wherein the benefits derived will warrant the cost of the installation.

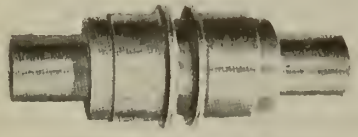
THE HANSON FRICTION CLUTCH

It is a well known fact that the majority of present day clutches are so large and heavy they have a tendency to cause trouble due to their weight alone and do not lend themselves to their ready incorporation into machine tools and other locations where appearance and reliability are matters of some consideration.

The clutch recently developed by the Hanson Clutch and Machinery Co. of Tiffin, Ohio, eliminates the cumbersome features of many older types and permits the installing of an extremely powerful clutch in very restricted locations. Its light weight, small size and neat appearance make it particularly adaptable to machine tool use.

Its capacity for transmitting large amounts of power is very great and where the outside diameter of a clutch is limited by design requirements the required horsepower can be transmitted. Takes the load gradually without a jerk owing to the double cone wedge expansion of the steel ring which grips the cylinder.

Several types are made. Fig. 1 shows a friction cut-off coupling by means of which a line shaft or any part of it may be cut-off or operated without interfering with the rest of the shop. As will be seen two coned friction disks engage



DOUBLE CLUTCH EXTERIOR.

with a double cone friction ring when the clutch is closed by means of the lever system actuated by the operator.

The clutch is adjusted by means of a threaded ring on the coned hub of the clutch. Its simplicity and positive uniform adjustment make it one of the simplest and most easily adjusted clutches and any unskilled workman can adjust it with success. All toggles are made of cast steel carefully proportioned and their complete enclosure by the guard renders the clutch extremely safe in operation.

The guard serves another useful purpose as it is used as an oil retainer, eliminating the necessity of constant lubrication, it being necessary to refill only every few months.

The clutch is thrown into and out of engagement positively and is locked in either position. It is impossible for it to engage itself even partially by centrifugal force.

In the friction cut-off coupling illustrated the ends of the shaft meet in the coned hub. This insures the absolute alignment of the shafts and a phosphor-bronze bushing is provided to carry the end of the extended shaft.

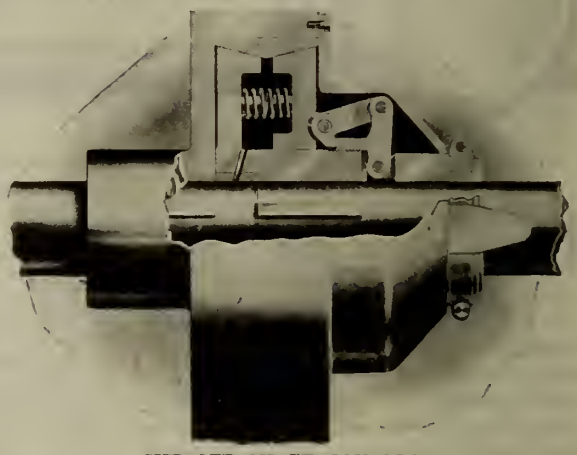
In the clutches used for machine tools and in other locations where small diameter is desirable a variation on the clutch above described is used. The operating sleeve engages with a wedge member, which in turn brings the two cones into engagement with the friction ring. As may be seen the resulting clutch is compact, cylindrical and perfectly balanced. All working parts are completely covered and are kept free from grit and dirt. The clutch can readily be adjusted to any desired tension without removing any parts by means of a single sleeve, which gives a uniform adjustment at all points around the shaft.

The double clutch shown in Fig. 3 requires but little more space than the single and is provided with two friction cylinders for mounting pulleys, gears, sprockets, etc., as desired, the dimensions of the sleeves varying to suit requirements.

Two varieties of friction surfaces are regularly applied. The standard surfaces are steel and iron bathed in oil and of long life. Where required friction surfaces are supplied of friction paper and steel. This type of clutch is designed for slow speed and heavy duty.

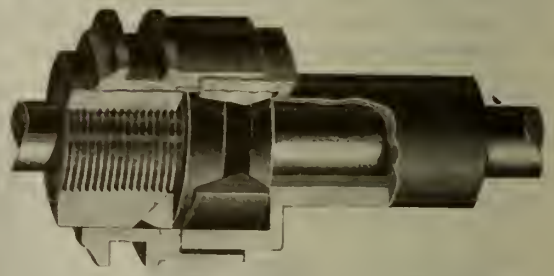
BURNING WASTE

Waste of the most unpromising character can often be burned with success and utilized in the generation of steam but special forms of furnaces are usually necessary in order to carry out the operation properly. Shavings, sawdust, bagasse, and spent tanbark are among the commoner forms of waste that are put to use in this way, and many cities are also generating steam by utilizing their refuse as fuel. The most important thing to do in burning waste, especially when it is damp or wet, is to handle the fires so that an abundant supply of air shall always be present, and a large surface exposed, over which the combustion can extend, and from which the water that the fuel contains can be evaporated. It is of prime importance, in handling wet material, to see that it becomes dried at least as fast as it is consumed; for if this condition is not fulfilled the dry part will burn up and the fire will then go out. In starting a fire that is to burn waste, it is usually necessary to run with some other kind of fuel until the furnace has become thoroughly



CUT OFF SHAFT COUPLING.

heated. The waste can then be added a little at a time, until the mass has become well ignited and a considerable part of it has become dry. Furnaces for burning waste are preferably detached from the boiler itself, the combustion taking place in front of the



SECTION SHOWING SINGLE CLUTCH ENGAGED.

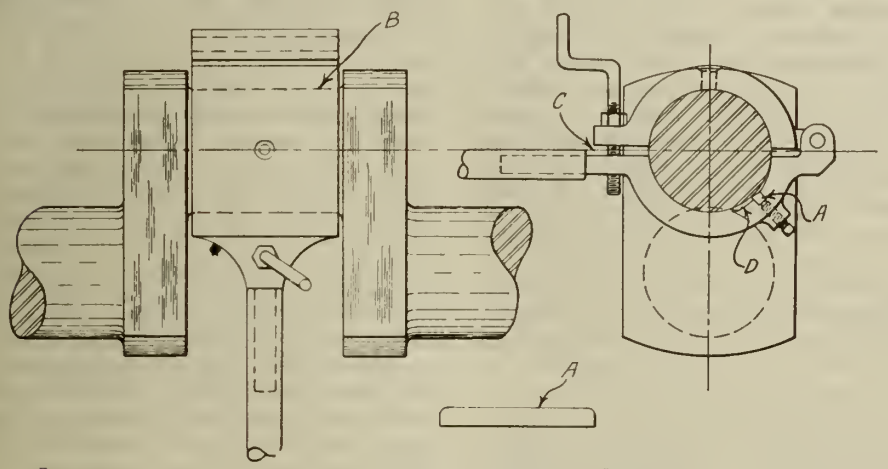
boiler, or below it, in a separate furnace from which the heated gases are led to the boiler by means of suitable fire-brick passageways. By conducting the operation in this way, it is possible to feed the fuel through openings in the top of the furnace—which is far better than introducing it through the doors in the front of the setting, as in firing with coal. The fuel should be thoroughly stirred up and worked over as it dries out and burns upon the grates, so that fresh portions of it may be continually brought to the surface. It is often best to handle the waste by a conveyor of some kind, the form of which will naturally depend upon the nature of the material itself. Blowers are used with good effect for handling shavings and dry sawdust. Considerable skill is required in order to burn wet waste effectively, and men cannot be expected to obtain first-class results until they have had the necessary training and experience.

The Operators' Point of View

ROUNDING UP WORN CRANK PINS

By A. L. MARSHALL

THE tool shown has given me so much satisfaction in rounding up worn cranks that I pass it along, hoping that it may be useful to others. The lower half of the tool-holder is made of machinery steel and case hardened; the upper half is of cast iron with a generous oil hole way cut through. The cutting tool at A is made as long as the crank is wide, while the body of the tool-holder is made slightly shorter. The hole is bored to the largest diameter of the crank pin B, with about 3-16 inch opening at C and the corners rounded to suit the fillets. In operation the tool-holder is clamped around the crank and as the tool-holder or the crank is revolved it is drawn together with the screw shown. A small set-screw near each end of the cutting tool serves for adjustment. The space D serves for the collection of the chips, and care must be taken that it does not fill up and score the pin. With a good supply of lubricant and a little care a crank can be rounded up in about 10 minutes. In this particular instance it might be stated that the tool was used on cranks for nail machine spindles, where the wear is chiefly on the high side of the crank and the little difference in throw did not matter.



RIG FOR TRUEING UP CRANK PINS

AN EMERGENCY GASKET CUTTER

By J. E. McCORMACK

AN emergency gasket punch was quickly made one day when we were cutting a gasket for a steam chest cover. The material used for the gasket was two or three ply sheet rubber, black, with cloth insertion. We wanted to cut holes in the gasket for size ⅝ bolts (if I remember right) and found no right size punch. The man who had formerly done this work had used his own tools, and, of course, took them with him when he left. While considering whether to use a knife or send for a new punch, one decided that "This will do when I get it sharpened a bit." His scheme was to take a piece of half-inch steam pipe, perhaps four inches long, screw a pipe cap on to one end and sharpen the edges of the other end. The method of using it was to place the sharpened end over the marked place on the gasket where a hole was required, then hit the tool on the other end with a hammer. A wooden block was used under the gasket to serve somewhat as an anvil, yet not dull the tool. The end of the grain of the wood uppermost gave the best results. The tool worked O.K. If the centre of the tool began to fill up with rubber pieces, they could be removed by unscrewing the pipe cap and poking the pieces out. I have used this scheme since for cutting holes in cardboard to make improvised coin cards, and with proper sized pipe it worked well for this also. Some variatin in the size of the hole it will cut can be made by the method of sharpening. Sharpening from the outside only will give a hole approximating the internal diameter of the pipe. Sharpening from the inside only, say by means of a drill, results in a hole approximating the outside diameter of the pipe, while a combination of these methods of sharpening gives an intermediate size. When sharpened from the inside the cuttings drop out, and of their own accord.

TWO VALUABLE TIPS

By J. E. N.

Most of us engineers have had experience with iron cements. Following is a formula which any reader can put together at any time. To join iron to iron for stove or furnace work, it is about perfect, and is just as good for iron joined together for outside work. It is practically impossible to separate iron cemented together with it, even if a sledge hammer is used. Take equal parts of sulphur and white lead and one-sixth proportion of borax; thoroughly mix them together; then take some of it and wet it with sulphuric acid; place a thin layer of it between the irons to be joined and press them together; let it set for five days, and no sign of the cement is left and the iron is practically welded together.

Probably thousands of your readers have made a mixture of flower of emery, etc., and used it to try for a razor edge. Of course, they secured poor results. Let them try the following mixture and they can put an edge on their knives, or their razor blades, that will be a joy and delight to them forever:

Take one ounce of levigated oxide of tin, one ounce of prepared putty powder, ¼ of an ounce oxalic acid, 20 grains powdered gum; make it into a stiff paste with water, and put a little of it over the sharpening strop. A few strokes of the blade over this will "do the trick."

It is ahead of most of the articles sold for the same purpose. A dab of moisture on the prepared strop will help to keep the paste on the strop in just the right condition for perfect work.

IMPROVISED DRAFTING COMPASSES

By J. E. M.

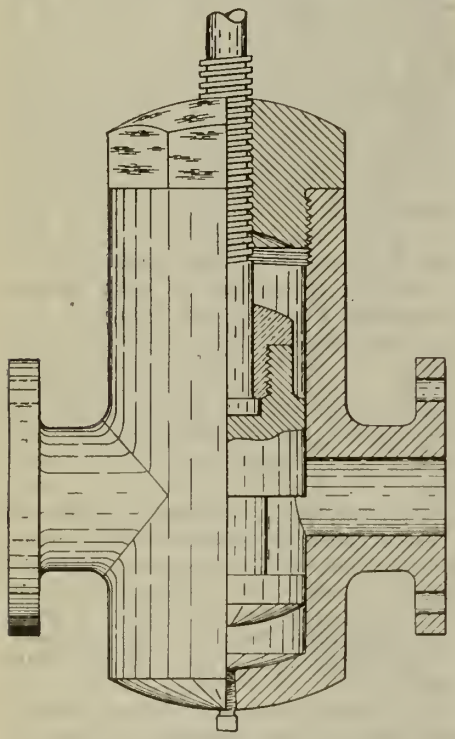
I wanted to draw upon paper some large circles in ink, but found that my drawing compasses were not large enough for the largest circles, but I had a pair of carpenter's compasses that were large enough; I also had what is called an accommodation writing pen. This consisted of a wooden handle, onto which was slipped a metal part made of thin sheet metal, and at one end so shaped as to receive the wooden holder, while the other end was so bent as to receive and hold the pen nib. I wrapped a piece of paper around the pointed end of one leg of the carpenter's compasses

until I had a bulk equal to that of the wooden pen holder where the metal part fitted onto it. I then removed the metal part from the pen holder and placed it on this leg of the compasses, still leaving the pen in place and turned the part so that the pen came into suitable position. I found that with this rig I could draw the desired circles. To ink the pen I dipped that leg of the compasses into the ink bottle. The object in wrapping the paper around the leg was to prevent the point of the leg of the compasses projecting too near to pen nib.

BOILER BLOW-OFF VALVE SUGGESTION

By K. WALSH

Blow-off valves have always been a source of more or less trouble to power plant operators, and the writer's experience has led him to offer the suggestion for a new design of valve that



DESIGN FOR BLOW OFF VALVE

would assist in overcoming some of the disadvantages generally encountered. In some respects, blow-off valves are subjected to more destructive abuse than any other unit of power plant equipment. Owing to the nature of its duties it frequently happens, when closing the valve, that a piece of scale will prevent the valve from properly closing, the result being the fireman will force the valve to its seat, often embedding the scale, the consequence, invariably, being a leaky valve.

The construction of the valve here illustrated removes some of these objectionable features; practically speaking there is no seat to the valve, as this consists of a piston sliding in a cylinder bored out to be a steam-tight fit for the plunger. The port through the valve at the time of closing. The close-plunger and the corners are left sharp to break any scale that may be in the valve at the time of closing. The close fitting piston prevents the steam or water from reaching the valve stem. Piston could be fitted with rings, if desired.

REPAIRING A DIPPER

By J. E. M.

A one quart dipper used in our department one day shed its handle. A new one was supposed to be sent for by the next messenger, but meantime a workman needed the dipper. Going to a box of the bifurcated rivets sold for mending harness, and also seen sometimes in narrow leather belts, he selected three to suit him, and with a hammer and sharp punch, soon had suitable holes through handle and dipper and had these rivets through and clinched. He made so good a job of it that the leakage was not noticeable unless watched for, and the dipper has since lasted as long as most of the new dippers last before losing the handle.

THE PRACTICAL JOKER IS A NUISANCE AND A SOURCE OF DANGER

MAY we be ever delivered from the practical joker in the power plant. His proper name is Fool, and his right place, a home for the mentally afflicted. Any man addicted to practical joking and allowing freedom to its call, should be driven from the power station as soon as the discovery is made. This does not refer to the "josser" or "jollier." A good-natured spoken joke or jolly is often a place promoter; for instance, if some man is somewhat slow in his movements when speed is wanted, it is generally possible to get him to hustle up by the proper application of a good-natured jolly; when, if a grouchy or curt order is given to speed up, it is quite possible the speed will increase, perhaps under a silent protest, with, perhaps, a mental determination to get back at the order giver sometime, somehow. I am not writing this article with no knowledge of the subject. I have had thirty years' experience in handling power plant employees. Many practical jokes are meant to be harmless, but they often work out the reverse way to that intended.

I remember seeing a man sitting in a chair tilted back against the wall in an engine room; a joker threw a burned-out 200 watt lamp which burst with a loud report under the chair, startling the sitter, causing him to upset the chair. His head hit the tile floor so hard that several weeks elapsed before he could resume his duties.

Another time at the General Electric Company's works in Canada a man was on a ladder; he was oiling shaft bearings, the top of the ladder being hooked over the shaft. A fellow worker thought it would be a joke to start the motor which operated the shaft, while the oiler was there. Just as the motor started the oiler placed his hand and arm through an iron pulley to reach an oil hole on the opposite side without moving the ladder. Result: a badly broken arm. In this case the man was not thrown from the ladder, the Lord only knows why, but he descended himself. I was at the bottom of the ladder, and to this day I am certain I heard the bone crack.

A workman connected wires to the two iron pulls on his tool drawer in such a way that anyone placing his hands on them would receive a severe electric charge. The manager came along and, standing with his back to the bench, placed his hands behind him and they came in contact with the drawer pulls. The shock he received knocked him insensible, and he was in danger of losing his life. Of course, the would-be joker was discharged and it was a close call to having to face a charge of manslaughter. It is an old joke and a mighty dangerous one to connect iron sinks in such a way that the user stands on a terminal and when he uses the fixture he receives a shock through the running water. While a fireman was taking a drink of water from the end of a hose line, the water being closed down so that only a thin stream was running; the joker came along and threw the water valve wide open; the fireman was thrown against the hot furnace doors and received several nasty burns. One joker loosened the set-screw holding a bushing on a governor pin on a steam engine direct connected to a D. C. generator; this made the engine pound and caused the lights to flicker very much; the engineer had to close down the engine, and it required some time to locate the trouble. This caused considerable annoyance to the manager by complaints from the light users, and the engineer got a call down for carelessness. Fortunately the joker had told several employees what he had done, so he "got his."

One day a new helper was taken on, a big husky fellow. One of the repair men thought it would be a joke to tell him to remove the bonnet from a two-inch valve while the pressure was on the pipe, it being cold water. The helper had a 36-inch trimo wrench and started to pull the wrong way; the joker did not attempt to put him right, he only laughed and told him to put more power to his pull; the husky helper did so to such good effect that he twisted the top of the bonnet from its screw. This ruined a perfectly good 2-inch valve. Incidentally the break was so unexpected and there being a high pressure on the pipe, both the joker and the jokee got a wetting.

And so it might go on. There have been jokes perpetrated in plants, meant

to be harmless, which have been directly opposite. No doubt lives have been lost and also much property lost through so-called jokes which have miscarried, and the guilty man never found out. Perhaps some perfectly innocent person had to take the blame. I remember a case where a joker, at night, removed one gallon of water from a five-gallon drinking water cooler in a factory, and replaced it with a gallon of grain alcohol; the result was that a number of the men got drunk on the job and were discharged; they also lost their name as reliable workers. Of course, they need not have drunk the mixture unless they wanted to; it seems to me that the so-called joker must have had some such idea of an ending in mind. The management offered a reward of $50 for the name of the joker; although he was known to several, no one exposed him. In this case justice miscarried, for he held his job, while his victims lost theirs.

Therefore, watch for him and when he is found in a power plant, "Scotch" him. He cannot be reformed, the disease is incurable, until the joker comes near his own death, or comes near killing someone else. Therefore, if you will not "fire" him, pretty near kill him at the first discovery.

JOHN PORT.

FEEDING BOILER COMPOUND

By R. MACLAREN.

In feeding boiler compound it is well to know when sufficient is being given. My method is as follows: — A testing mixture is prepared by stirring into a gallon of half alcohol and half water one ounce of phenolphthaleine.

The latter may be obtained from a druggist, and if you will read the police court columns of the newspapers you will probably find out where to obtain the alcohol.

A sample of water is drawn from the boiler.

If it is drawn from the try cocks care must be taken to see that enough is blown out of the column so that the sample will be from inside the boiler. A few drops of the testing mixture are dropped into the sample.

If sufficient compound is used the water will turn red.

As too much compound will make a boiler foam, it is worth while knowing the condition of the water.

One of my boilers once had an exceedingly bad attack of foaming.

The test showed only the proper amount of compound.

Investigation of the boiler disclosed the fact that the furnace gases were short circuiting through a hole just below the lower water column connection, and causing the water in the column to boil. As it might be difficult for some to get half a gallon of alcohol, a few ounces of the mixture in the ratio given will do as well.

Some Paragraphs About Steam and Boiler Operation

Coal shortages drew attention to a great many leaks that were turned into economies and raised the general average of the amount of water evaporated per pound of coal, which is the real function of every well-run boiler. Some facts on steam, evaporation, and condensation follow. Not only have the men in charge of boilers and engines learned more about these very facts, but those who are only indirectly concerned have evinced an interest in a most important subject.

* * *

One cubic inch of water evaporated at atmospheric pressure (15 lbs.) becomes one cubic foot of steam, approximately.

* * *

Boilers that are well designed and carefully operated will evaporate from 7 to 10 lbs. of water for every pound of coal burned—poor qualities of coal will reduce this amount considerably.

* * *

Every square foot of heating surface in a boiler is sufficient to evaporate two lbs. of water. This is the average basis of calculation and may vary with the operation. In figuring the size of boiler for a given engine whose consumption of water per horse power per hour is known, the boiler should have ½ sq. ft. of heating surface for each lb. of water consumed per H.P. per hour.

* * *

Wood has been burned largely during the past two years: its comparative value may be stated by saying that 9 lbs. of dry wood is equivalent to 4 lbs. of good steam coal.

* * *

The consumption of coal for a boiler may be roughly figured by knowing that on every square foot of grate surface there can be burned an average of 18 to 20 lbs. of soft coal or 10 to 12 lbs. of hard coal per hour with ordinary stack draft.

* * *

Engines are said to consume so many pounds of water per hour as stated above—really they consume the steam that is evaporated from the water, but as it is water (not steam) that is bought for a boiler, this form of statement is usual. Different types of engines consume from 12 to 52 lbs. of water per H.P. per hour, and from 1½ to 7 lbs. of coal.

* * *

The first cost of condensing engines and outfit is, of course, greater than for simple non-condensing engines, but the economies of operation make up for this cost in a short period. A good condenser will save approximately 1-5 of the fuel to be consumed, or it will increase the power of the engine 1-5 for the same amount of fuel used.

Condensing engines require, on the average, twenty-five times the amount of water for condensing purposes that is needed for boiler feed; this, of course, is not consumed as is the feed water. For the average engine from 1 to 1½ gallons of water per minute per H.P. is needed for condensing.

* * *

Surface condensers for compound engines require approximately two square feet of cooling surface per H.P. Surface condensers for simple engines require more surface per H.P., the amount varying with the economy in use of steam.

* * *

A good condenser and a good air pump should show 25 inches of vacuum. This will make available 10 to 11 lbs. more mean effective pressure (M.E.P.) with the same terminal pressure, or stated another way, it will give the same mean effective pressure with a correspondingly less terminal pressure.

To get results and economy with condensers it is always necessary to set the air pump lower than the condenser.

CHIMNEYS AND STACKS

Chimneys and stacks should have a capacity considerably in excess of the normal needs of the plant, in order to provide for temporary overloads and for future increases in the number of boilers. Brick or sheet steel may be used in their construction, the choice being governed mainly by the relative cost of construction and maintenance, and often by location and architectural considerations. Brick chimneys, when properly designed and constructed, are quite permanent and need but little repairing. They should have an inner lining, entirely separate from the outer portion, and preferably extending to the very top or nearly so. This lining is made thinner than the outer wall, because it does not have to resist wind pressure. It serves to protect the outer wall from the heat, thus preventing the formation of cracks from uneven expansion and from the chilling action of rain. The lining should be made of fire-brick, to its entire height: and it should preferably be laid up with fire-clay. Brick chimneys, like brick settings, often leak air sufficiently to damage the draft to an appreciable extent. The same possibility should be considered in connection with steel stacks also, and their joints should be calked at all points, in order to keep the leakage down as much as practicable. This precaution is often neglected, and the efficiency of the stack is correspondingly reduced. Leaks in or around the smoke flue should be promptly detected and stopped, and special attention should be given to the points at which this flue enters the chimney or stack. Steel stacks are often made without any lining of brick, but such a lining is to be strongly recommended, because it tends to prevent corrosion of the stack on the inside, and it also reduces the radiation from the stack and in this manner improves the draft.

BOOK REVIEWS

Steam Engines, By E. M. Shealy, the McGraw Hill Book Co.—This book on steam engines was written as a text book for correspondence students in the University of Wisconsin. It is the third of a series of three text books designed for those students who are pursuing a general course in steam engineering, the other two being "Steam Boilers" and "Heat." The fundamental principles underlying the operation of the steam engine are taught in as simple and non-mathematical a manner as possible. Enough of the practical features of steam engine operation has been given to illustrate the principles involved; that part of the course dealing with valve gears has been made more complete than other sections because it has been found that operating engineers usually do not understand the valve gear mechanism of their engines as well as they do other parts.

Contents: Principles of the steam engine, Corliss and other engines, parts of the steam engine, heat work and pressure, properties of steam, indicators, indicated and brake horsepower, action of steam in the cylinder, steam engine testing, the slide valve, the valve diagram, valve setting, shifting eccentric and the Meyer valve, reversing mechanisms, Corliss valve gears, governors, compound engines, condensing apparatus, lubrication, steam turbines.

For the engineer who wishes to obtain a reference work or for the student wishing information on the principles and operation of the steam engine this work should prove quite welcome.

The Practical Telephone Handbook, by J. Poole, 7s. 6d., Sir Isaac Pitman and Sons, Ltd., Amen Corner, London.—The present edition of this work has been completely revised and largely rewritten with the incorporation of much additional material relating to the later developments in telephone engineering. The contents have been brought in line with the British Post Office practice. The various subjects dealt with embrace the whole field of telephone engineering and the automatic telephone exchange is described in detail, great advances having been made in its use, particularly in England and on the Continent. This work is intended as a handbook for those having to do with the operation of telephones. exchanges, line construction, etc., and the subject matter has been prepared with this end in view.

The various types of telephone systems adapted to various uses including the now almost universally adopted central energy system are described in detail, together with much descriptive matter regarding the apparatus itself. The modern exchange, multiple switchboards, junction line working, trunk line working, party line working, and other systems are dealt with. The supply of power for the operation of the central energy plant is taken up in a chapter which deals with the apparatus used and its arrangement for the continuous supply of power. Pole line and underground construction are thoroughly dealt with.

One of the more recent devices which have made long distance telephony possible is the system of Pupin loading coils, which enable the inductive characteristics of the circuits to overcome capacity effects. Transmission line calculations are given in the section devoted to this phase of operation. Multiplex telephony and the use of phantom circuits are dealt with together with the use of submarine cables. As the subject of telephony needs for its elucidation at least an elementary knowledge of electrical science, and in order that the book may be of service to the general public, the author has considered it advisable to define the various electrical terms which will be met with in the descriptive matter, and to give a short sketch of the science. Telephone employees, for whom the book is chiefly intended, should find it of value and of interest from the standpoint of European practice as well.

A Handbook of Physics Measurements, in two volumes, by Ervin S. Terry, John Wiley and Sons, Inc., New York, and the Renouf Publishing Co., Montreal. Price $2.00 per volume.

The aim of these works is to furnish the student of pure or applied science with a self-contained manual of the theory and manipulation of those measurements in physics which bear most directly on his subsequent work in other departments of study and upon his future professional career. While primarily intended for the student in the universities, the text has a wider application and will prove of value to those in engineering pursuits who have occasion to use the principles of general physics in their application to optics, heat, harmonic motion, sound and electricity and magnetism. A useful portion of the first volume treats of the general principles underlying physics measurements and the theory of errors, required accuracy of measurements, approximate formula and the graphical representation of results are dealt with. The properties of matter are dealt with in the following chapter, together with the measurements employed. The remainder of the first volume is devoted to optics and to a set of physical tables. The second volume gives those measurements of quantities in vibratory motion, sound, heat, electricity, and magnetism, which experience has shown to be most available for college and industrial laboratories. Much consideration has been given to the particular determinations now demanded by science and industry. In addition to the standard experiments in heat, the mechanical engineer will be especially interested in the methods given for the determination of the economy effected by steam pipe coverings, the thermal value of coal and the thermal value of gas.

All the physics determinations in electricity and magnetism ordinarily made by students in electrical engineering are described in detail and in addition considerable space has been devoted to work on damped vibration and harmonic wave analysis. This work is of importance in the study of alternating current phenomena. As in the first volume each chapter consists of two parts. The first includes definitions, a description of the apparatus, the general theory of the methods and the derivation of the equations used in the determination of the quantities considered in the chapter. In the second part of the chapter each determination is described in detail with respect to the theory and manipulation of the experiment, and the computation of the result.

MECHANIC'S AND DRAUGHTSMAN'S POCKET BOOK

Sir Isaac Pitman and Sons, Ltd., London, have published a pocket handbook of the above title for use of draughtsmen, mechanics and others, who have frequent need of some reference work for the recalling of formulae, etc., used in every-day work. W. E. Dommett, the author, in his preface states that the work, notes and diagrams are not intended to replace text-books, but to act as a means for refreshing the memory in cases where the latter has become imperfect. Mathematical tables are given in compact form and include squares and cubes of numbers, square and cube root, temperature conversion tables, areas and circumferences of circles, trigonometrical functions, tapers and angles and logarithms.

The above tables are those usually found in works of this type, and in addition to these some extremely useful tables are given, which are seldom seen. These have to do with the coefficient of friction of various materials, revolutions of wheels or discs per minute, and the centrifugal force exerted by a rotating mass of one pound, at various speeds, etc.

Wire gauge tables, specific gravity and other weight tables, thread tables and other tables dealing with the properties of materials are included.

The sections dealing with trigonometry mechanics, statics and logarithms, together with that on mensuration, are of particular value, and while the book is of 125 pages, much information of real value has been condensed into a small space and the book should prove a welcome addition to the reference library of those who have occasion to use material of this nature.

WATCHING FUEL WASTES

Sometimes the managing head of a manufacturing concern is not alive to the needs of the power plant because he does not understand the dollars-and-cents possibilities that it offers. When the engineer cannot get what he knows the plant needs, he loses interest in the welfare of the department of which he is in charge. One rather extreme case of this came to the attention of a salesman for a house that manufactures power plant supplies.

NON-CORROSIVE
CYLINDER OIL
MANUFACTURED ONLY BY
E. H. KELLOGG & CO.
NOS. 242 TO 244 SOUTH ST. NEW YORK, U.S.A.
FRICTION LOSS

An overload is often a necessity. But it is hard on an engine. To successfully carry an overload so that there will be no after effects on the engine a very careful selection of your oil should be made. An oil that is not free from impurities will cause a greater wearing on the bearings, a great friction loss will occur. You will need to fire the boiler more often because the engine will be harder to run. In this manner you lose out. You work harder, have larger operating costs, and less power all because of your oil. Do as a great many Canadian engineers have done—give Kellogg's "Non-Corrosive Cylinder Oil" a trial. Absolutely pure. Write us regarding it.

E. H. KELLOGG & CO.,
New York, U.S.A.

American Manufacturer Wants Representation in Canada

Our proposition should interest an established machinery supply house now calling on steam power plants in Canada. For particulars, write Box 161, Power House.

(H) P.H.

"See our chief engineer about the matter," said the general manager to the salesman. "We leave all matters of fuel economy to him."

"Leaves all such matters to me, does he?" said the engineer when the salesman called on him. "If he only did leave them to me there would be something doing. Last week I went to the office with a requisition for a feed water thermometer. I was turned down. He said we must 'economize.' I told him that was what I wanted to do and why I wanted the thermometer. I tried to explain that every 10 degrees added to the temperature of the feed water meant a saving of 1 per cent. in fuel.

"What do you think he said to me? He asked me if the thermometer would make the feed water any hotter!

"I told him that I could not heat water with a thermometer, but that the particular thermometer I wanted would tell me where I was 'at'—which was more than I knew at present. Did I get that

WANT COMPETENT ENGINEER TO LOOK AFTER SCHOOL BOILER PLANTS

"THAT there should be greater efficiency and safety from proper inspection of the boilers in the Toronto schools is the contention of many of those who have been following the case for some time. In the schools of Toronto there is consumed about 20,000 tons of coal per year, and the contention is that by proper inspection there could be a very material saving. In fact one of the trustees who is going into the matter very thoroughly makes the statement that it would be possible to pay $3,000 per year to an engineer to act for the board and then show a saving of $7,000 per annum, as well as having a greater margin of safety in the operation of the plants. The Toronto branch of the C.A.S.E. have taken the matter up and have assured Trustee Bell that he will have their sympathy and support in the matter.

The case, as stated to POWER HOUSE by one of the Toronto engineers, is as follows: At present, those in charge of the plants have nothing in the examinations they have to pass to show for efficiency, that is, proper combustion and general economy in the boiler room. The caretakers in most cases are paid so much per room for cleaning, etc., but in most cases they have to engage a fireman or engineer to run their heating plant during the winter months as they have no time to look after it themselves. Of course they are out to engage a man for as little as they can get him. In case the plant runs under 20 pounds pressure or is under 50 horsepower, any person can be taken on without papers, but above that size papers are required for the man who fires the boilers. The engineers contend that there should be a competent engineer to superintend these plants. The papers that are set at present have some twenty-four questions, and they cover only the rudiments of boiler and plant operation. In regard to the attitude of the C.A.S.E. in the matter, one of the officials of this organization stated:

"We have no axe to grind in the matter. We are interested because the matter comes directly into our field and because many of us are ratepayers with children attending school. The matter was discussed at one of our meetings and we decided that we would back up Trustee Bell because we felt that he is right in this matter. We would urge the appointment, and ask simply that it should be made on the merits of the case and entirely removed from any political or ulterior influence. It would also be well to have such an inspector of boiler plants acting separately from any other official, and he should be allowed to make his report directly to the Board of Education."

London.—The Canadian Government has signed agreements with Greece and Belgium, advancing $25,000,000 to each country for the purchase of Canadian goods. It is expected an agreement with France will be signed shortly.

Agreements with Serbia, Poland and Bohemia cannot be negotiated until the Peace Conference defines boundaries of these countries and guarantees stable Governments.

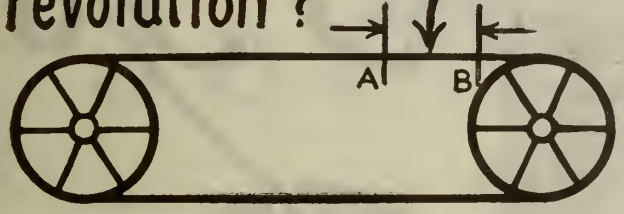
We Want a Mechanical Engineer With Sales Experience

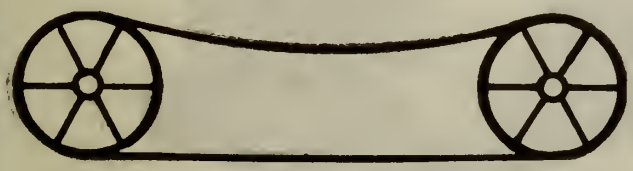
—a man who can give his entire time to selling a widely advertised power house device. An intelligent, convincing talker, a man not afraid of work, a man who expects good pay for good work, is the man we want. We will respect your confidence. In the first instance, write fully to Box 160, Power House.

(E) P.H.

Does your belt slip this much each revolution?



Do you know how much your belt slips? Have you ever tried to find out? Belt slip is a thing that every belt man should know all about.



Perhaps your present belt slip is a serious matter but you don't know it, because you have never studied your belt.

Listening and looking at a belt are not enough. Actual MEASUREMENTS AND COMPUTATIONS should be made.

Perhaps your belts are too tight. Tightness does not necessarily stop belt slip. By treatment with Cling-Surface and increasing the arcs of contact slip can usually be entirely eliminated.

CLING-SURFACE--- What It Is and What We Will Do For You

Let us diagnose your belt troubles. At least let us help you. Tell us the exact diameter of your driven and driving pulleys in inches; the thickness of your belt, inches; the revolutions per hour of your driven and driving pulleys; the width of belt, inches, and distance between shafts, feet. Give us ACCURATE information. We will compute your belt slip and tell you if Cling-Surface will improve matters.

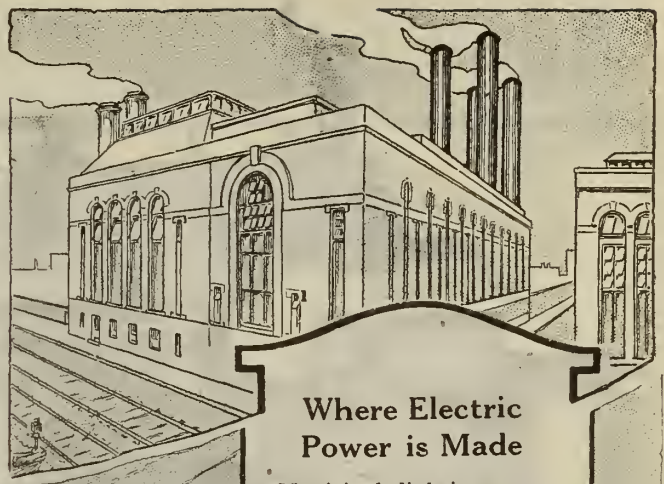
Cling-Surface is a sensible, logical, engineering treatment. It is not sticky. It BENEFITS the belt. Lengthens life. Waterproof. Makes the belt pliable. Enforces intimate contact.

The sooner you write to us the better, for as soon as Cling-Surface is applied, coal, labor, time and money begin to be saved.

Cling-Surface Co.

1057 Niagara St. - BUFFALO, N.Y.

Send orders to above address and delivery will be made from Toronto or Montreal stock. F.O.B. those points duty paid



Where Electric Power is Made

Municipal lighting companies take no chances when buying equipment. As current must be supplied uninterruptedly, every precaution is taken against shut-downs.

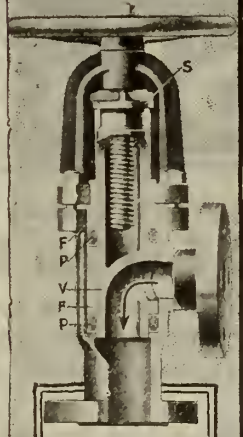
Take corporations such as

Montreal Light, Heat & Power Co., using 24.
Cleveland Elec. Ill'g. Co., using 178.
Edison Elec. Ill'g. Co., Brooklyn, using 100.
Potomac Elec. Lgt. & Pr. Co., Washington, D.C., using 24.
Duquesne Lgt. Co., Pittsburgh, using 34.
Omaha Elec. Lgt. & Pr. Co., using 97.
Worcester Elec. Lgt. Co., Worcester, Mass., using 36.

Each has its boilers equipped with from 24 to 178 YARWAY (formerly Simplex) "Seatless" Blow-off Valves—a choice that in effect, becomes a recommendation of the very highest character. In the YARWAY (formerly Simplex) there are no seats or discs to cut, clog or grind down. There are no pockets to gather sediment—no obstructions of any kind. The port is free and wide open. Packing is protected and will last for years.

Other good points may be learned by trying a YARWAY for 60 days. It may be returned if not satisfactory.

Write for one to-day, stating size of line and whether screw or flange, angle or straightway.



Operation:

In closing valve, shoulder "S" on plunger "V" engages the loose follower gland "F," compressing packing "P" above and below the port, making an absolutely tight valve.

Jacklift

—your way to lower labor costs and bigger profits

It can be done—that's why so many in the United States are using the Jacklift and the platform system for handling heavy loads. And now the Jacklift is being made in Canada for Canadian manufacturers who wish to reduce their inside trucking costs.

The Jacklift and platform system in your plant means the easier handling of loads, the quicker movement of materials, less labor, greater economy and less possibility of accidents or damaged materials.

Four Vital Points of the JACKLIFT

High Lift

A clear lift of 2½ inches by four easy strokes of the handle operating an ordinary jack.

Easy Lift

Four times the handle movement means a lifting ratio of 1 to 35. A girl or boy can easily handle one of these machines with heavy loads.

Angle Lift

The handle will operate at any angle up to 90 degrees either side as easily as straight away. This is impossible with any other truck.

Straight Lift

The Jacklift raises and lowers the load in a straight line—a great convenience, as every other truck operator will tell you.

These four vital points, not contained in any other truck, place the Jacklift in a class away above all competition, and yet the price is practically the same as the other machine.

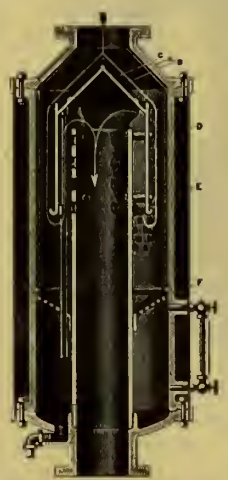
III IMPORTANT THINGS
TO CONSIDER ABOUT A SEPARATOR



I. THE PLAN—Is it sensible, will it work, no matter how large the Separator or how well made?

II. THE SIZE—Is it big enough regardless of plan, will it hold a good dose of water?

III. THE CONSTRUCTION—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

GRATON & KNIGHT
Standardized Series
LEATHER BELTING
Tanned by us for belting use

HERE *is pictured a 75 foot Graton & Knight Heart Brand Belt in the plant of the Model Mill Company, Johnston City, Tenn. It is* 24 *inches wide, double-thick. It transmits* 241 *Horse Power. It has been in continuous hard service for five years. Its cost per week has been* $1.35, *or five mills per horse power, per week.*

Power and the Right Material

Leather is the right material for belting. It is firm. It is strong. It has permanent power of expansion and contraction. It is tough, but it yields in the *right* degree, at the right time. It is easily and repeatedly spliced or repaired. It stands mauling by shifters. Side-slapping won't fray it. Even after long use it can be cut into narrow belts and goes on with its good work.

Leather stands alone as to these characteristics. It is Nature's contribution to power transmission needs. No other known substance is like it in wearing qualities. And no other belting material successfully replaces it.

There is no mystery about the quality of the leather in Graton & Knight Standardized Series Belts. It's in the *tanning*—an operation based on the *work to be done.* The yearly output of our tannery is nearly 300,000 hides. That makes *you* sure of uniform quality for any given specification. For there is a wide scope of selection from such a mountain of leather.

Graton & Knight Standardized Series Belts are made to give the longest possible service at the smallest possible cost. Those who use them say that they do.

Many of the best-belted plants ask us to specify the belting for every drive. Try the plan yourself. Then, when buying, call for "Graton & Knight Brand — or equal." This won't commit you to buying our belts. It will put your buying on the one basic consideration — the work to be done.

Insurance Against Shutdowns—

JEFFERSON UNIONS

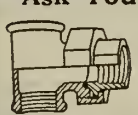
Backing up the engineer in his effort to boost production to top-notch records you'll find JEFFERSON UNIONS. Big production requires steady, uninterrupted service, steam lines that carry great variations in the load and air lines that deliver full pressure under all conditions of service.

JEFFERSON UNIONS are to-day, as in the past, meeting exactly every requirement of severe service. They are constructed extra heavy of the highest quality materials—a feature that insures the continuous perfect service so essential in the power plant.

Be sure to get JEFFERSON—the name on the nut protects you from the "just-as-good" variety and costly break-downs.

Ask your jobber to show you JEFFERSON Unions to point out where they are different. Our new Catalog, "UNIONS," describes the complete JEFFERSON LINE. Write to-day for your copy.

Ask Your Jobber About These Jefferson Specials



Union Tee, with union on the outlet. Made also with male end on outlet.

Male and Female Union. Does away with a nipple, and makes a short connection.

Union Elbow with 45° angle. Also made male and female.

JEFFERSON UNION COMPANY

Lexington, Mass.

P.H.

Williams "Agrippa" Chain Pipe and Fittings Wrench

THEIR narrow, single jaw, with saw-tempered teeth for file sharpening when worn, gives these wrenches unequaled facility for holding and turning cramped and irregular fittings, flanges, short nipples, etc., etc., because:—

They grip upon surfaces where ordinary tools cannot—"Their grip does not slip."
They do work which tools with broader jaw will not.
They give more and better service than any screw-adjusted wrench made.
They "start" rusted fittings when all else fails—just the service to be logically expected of a fully warranted tool.

Remember, each Chain, like those in our well-known "Vulcan" Wrenches, is "proof-tested" in a standard tension machine to two-thirds of its catalog strength, and is certified. We guarantee absolutely every tool that leaves our factories. 7 sizes for ⅛ to 12" pipe and fittings.

Your dealer will serve you. Ask for Booklet.

24 Years Carrying 50% Overload

TEN years ago the U. S. Rubber Reclaiming Co. of Buffalo installed a 50 H.P. Link-Belt Silent Chain Drive. That drive has been operating ever since, 24 hours a day carrying a 50% overload. If figured on the basis of a ten-hour day, that drive has been in operation 24 years.

Think of it. Twenty-four years of driving efficiency—unaffected by heat, cold or dampness, carrying 50% greater load than was intended—with never a slip, the load always cushioned and never a moments idleness for chain repairs. That's Link-Belt Silent Chain Drive efficiency and service. It will prove itself "flexible as a belt, positive as a gear, more efficient than either" in your plant. Let us prove it.

Our many years of Power House experience is at your service to help you save money in the transmission of your power. Write us. Ask for our Data Book No. 125.

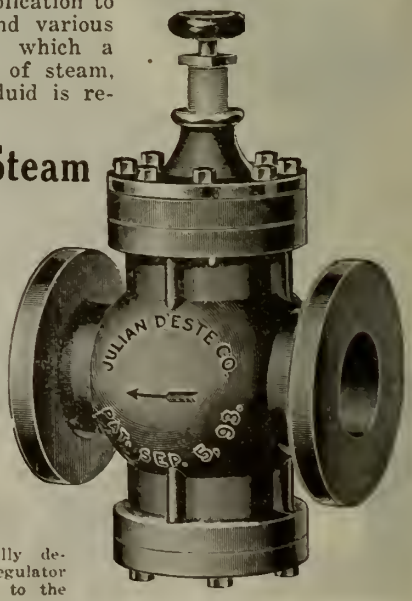
CURTIS Engineering Specialties

Universality!

For universal application to all the varied and various conditions under which a reduced pressure of steam, water or other fluid is required the

Improved Steam Pressure Regulator



has no equal.
It is compact and self-contained, without levers, weights or projections.
No glands or packing; no drip or leak of steam or water. Suitable for any boiler pressure; made entirely of metal: is a lock valve, very simple and sensitive.
Send for leaflet fully descriptive of this Regulator (contains price list) to the manufacturers.

A Timely Service --- and the Company behind it

The public wants better steam heating service—more comfort per ton of coal. This Company is in a most favorable position to meet this demand through its co-workers—the architects, heating and ventilating engineers, heating contractors and builders—to whom it offers practical co-operation that will increase their prestige as well as their volume of business.

Any man who uses, specifies or installs steam heating equipment will find it advantageous to learn more about Dunham Heating Service—the product of 15 years' knowledge of steam heating in all its phases.

822 POWER Vol. 48, No. 23

Coal Saving by the Scientific Control of Steam Boiler Plants*

By D. Brownlie

THE author has been associated for about ten years with the investigation on scientific lines of the working of every description of steam-boiler plant, and in the present article it is proposed to give the average figures for 250 typical steam boiler plants, with the object of supplying accurate data as to the tremendous national economy that can be effected by the adoption of scientific methods in the boiler-house.

In the burning of coal for the generation of steam, the loss because of lack of scientific methods is hardly realized and, apart from the national point of view, offers to the individual firm a means of most substantial economy in running expenses.

It is not possible to find out what is the exact amount of coal used for the production of steam for purposes other than power, there being, for example, no statistics available showing the number of steam boilers at work in Great Britain.

The author proposes therefore to assume, until further information can be obtained by a proper engineering census of the country, that the total amount of coal used for steam generation in the United Kingdom is between 75 and 100 million tons per annum, being 60 to 70 million tons for power production and 15 to 30 million tons for purposes other than power, corresponding to 40 per cent. to 53 per cent. of the total coal used, and is of the opinion that the 250 boilers to be dealt with in the present article are really representative of all the boiler plants of the country, and the results of such a very large number of exhaustive investigations carried on continuously during [illegible] us to judge with co[illegible]

rine" boiler, 2 "vertical" boilers, and 3 "patent" boilers difficult to classify. It would be most interesting to know the exact number of each type of steam boiler at work in the country, although there is no doubt that the chief type in use is the "Lancashire."

Amount of Fuel Used—The average shows 20.9 lb. of fuel burnt per square foot of grate area per hour, referring, of course, to the average amount burnt per hour per working day, and not to the amount for any particular hour. This figure is considerably below what is possible on a boiler plant run on modern lines, which would burn something like 25 lb. to 30 lb. per square foot grate area per hour with the average quality of fuel. The boiler plants of the country are working under very easy conditions in this respect, and much more fuel could be burnt per boiler. Figures for fuel consumption depend largely on the quality of the fuel. Thus a good quality washed coal of, say, 13,000 B.t.u. and 7 to 8 per cent. ash could easily be burned economically at the rate of 35 lb. per square foot per hour, whereas purely refuse coals would only give [illegible] Coke of good quality can be burnt [illegible] per square foot grate [illegible] 15 pounds.

[illegible] to the effluent from some other works.

Economizers—Out of the 250 plants, 155 were fitted with economizers, the other 95 plants having no means of utilizing the waste heat from the boiler flues.

Taking the 155 plants fitted with economizers, the average saving is 11.4 per cent. of the coal bill. The highest figure found was 19 per cent. on a cotton-mill plant. The ordinary figure obtained on a well-managed plant is 15 to 20 per cent. saving, depending on the conditions.

Estimation of CO_2—Out of the 250 plants, 225 [illegible] not [illegible] CO_2 recor[illegible]

How Dominion Rubber System Belting Service Helps Belt Users

For more than fifty years we have specialized in the making of belting and the solving of problems in transmitting power and conveying materials economically.

We maintain a staff of belting experts for the sole purpose of helping Canadian Manufacturers to "speed up" production by cutting belting costs and eliminating power wastage.

These experts will, without charge, analyze your transmission and conveying equipment in its entirety and will recommend changes only where they are necessary to increase the efficiency of that equipment.

You are under no obligation to us in availing yourself of this service—the only return that we request is that you purchase Dominion Rubber System Belting when you have been convinced that the changes recommended by our engineer will be beneficial.

This special service is available through any of our branches.

Phone, wire or write the one nearest to you and let us prove to you that the kind of service we have given to Canada's largest industries and the kind we want to give to you, means more then just selling better belts.

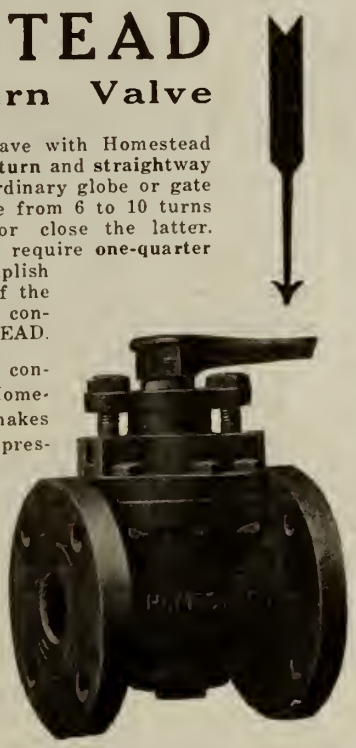
Just One Quarter Turn

Opens or Closes This HOMESTEAD Quarter Turn Valve

Think of the time you save with Homestead Valves with their **quarter-turn** and **straightway** opening, compared with ordinary globe or gate valves. It takes anywhere from 6 to 10 turns of the wheel to open or close the latter. HOMESTEAD Valves just require **one-quarter** of one full turn to accomplish the same result. Think of the time saved—think of the convenience of the HOMESTEAD.



Homestead Valves are all constructed with the patent Homestead Principle which makes them seatless while the pressure is passing through, thus they are operated easily and safely.

Made in Straightway, Threeway and Fourway patterns.

Homestead Valve Mfg. Co.
Homestead, Pa.

When Buying Thermometers There's Just Three Things to Remember—

First, you must have accuracy and sensitiveness—

Second, durability is absolutely essential—

Third, the thermometer must be suitably constructed for the intended application.

Accuracy, sensitiveness and durability are absolutely guaranteed in

"Crescent" Thermometers

And with nearly seventy years of experience to our credit, we are qualified to properly interpret your needs.

Our Catalog P.H. 200 illustrates and describes "Crescent" Thermometers for every application. Also test thermometers, glass thermometers, etc.

Get a copy of Catalog P.H.-200 to-day.

Play Safe!

Guard against the possible destruction of life and property.

THE
LUNKENHEIMER "VIGILANT" WATER COLUMN

will protect the boiler against the dangers incident to low or high water levels by automatically sounding an alarm when the water level approaches either danger limit.

It thereby safeguards life and property, and by aiding in maintaining a uniform water level contributes to economy in the use of fuel.

It has demonstrated its reliability in service, and is specified where safety and economy are paramount

For working steam pressures up to 250 pounds; in a variety of sizes to suit all makes of boilers.

Specify LUNKENHEIMER "VIGILANT" and insist on its installation.

★STEFANSSON'S
OWN STORY *of his*
FIVE YEARS *in the* ARCTIC

Over five years ago Vilhjalmur Stefansson, the famous Arctic explorer, was commissioned by the Canadian Government to lead a party into the uncharted space that extended from the north-westerly boundaries of Canada on to the North Pole. Shortly after the party got away the news came back to civilization that Stefansson and some of his party had drifted out into the Arctic seas on an island of ice and they were given up as lost. But Stefansson came back, safe and sound after four years of amazing adventures, during the course of which he made many discoveries of scientific and geographical value. Mr. Stefansson has written his story of this wonderful journey and exclusive Canadian rights have been purchased by MACLEAN'S MAGAZINE. It starts in the April issue and will continue for six months. It is a thrilling narrative—unquestionably the most important Canadian story of the year.

★ **Stefansson's story will be published exclusively in Canada in MACLEAN'S. The series of articles by him, now appearing in American and Canadian newspapers, refer entirely to his experiences on previous explorations and do not deal with the journey that he undertook for the Dominion of Canada and completed last year.**

Other Outstanding Features of April MacLean's

"Imperial Relations Must be Worked Out," by Viscount Bryce. An important announcement on the future construction of the British Empire.

"Reconstruction in Turkey," by Stephen Leacock. A humorous article on the present condition of things in Turkey as seen by Canada's great humorist, and applied to Canadian conditions.

"Bulldog Carney," by W. A. Fraser. A splendid novelette of the Canadian West, complete in this issue. Illustrated by Charles L. Wrenn.

"Opening the New Book," by J. K. Munro. An article on the situation at Ottawa created by the new Liberal leadership—smashing, impartial, fearless.

"The Sun Gazer," by Charles G. D. Roberts. A remarkable animal story. Illustrated by Artheur Heming.

"Canada's Fishmonger General," by Thomas M. Fraser. An article on a young Canadian who put Canadian fish on the diet of the British armies by a series of Barnum and Bailey advertising stunts.

"Bombing the Boche," by Lieut. J. Vernon Mackenzie. The second of the two articles that Mr. Mackenzie has written on the whirlwind campaign of raid reprisals which so frightened all Germany.

"The Transformation," by Frederic S. Isham. Illustrated by Hanson Booth. The second instalment of this sparkling new serial.

"Man and Wife," by C. W. Stephens. Illustrated by R. M. Brinkerhoff. The first instalment of a three part story of Canadian life by a new Canadian writer—a delightful love story with a background of business intrigue.

The Review of Reviews

The best articles from all publications the world over are selected and condensed for this department. Some of the articles in the April number are:

The Man Behind Bolshevism.
Could German Fleet have been Destroyed.
The Secret Plans of the Allied Command.
Too Much Wilson.
Is the ex-Kaiser Haunted?
Next Government Will be Labor.
New Life of Deposed Princess.
A New Kind of Socialism.
Are We Communicating With Mars?
The Cohort of the Damned.
Has War Wiped Out Disease?
The Red Terror in Russia
The Sultan Takes Hold.
Some Tricks of the Mediums.

Magnolia Metal Co.

Gentlemen:—I have used MAGNOLIA METAL for the past TWELVE years, both on low-speed, heavy duty and on high-speed Planing Mill Machinery, always with excellent results. The most severe test during these years where MAGNOLIA METAL demonstrated its worth beyond question, to me, was on bearings on three Dredgers operated by the South American Government at Rio de Janeiro; the main rods, cranks, and tumblers constantly working under water where there was a considerable quantity of grit and sand.

I was in charge of work at the above point, also the dredging work, Morevella, State of Menas, for almost ten years, and at all times MAGNOLIA METAL gave A1 results.

Yours very truly,
A. J. POWELL.

Don't buy that New Electrical Apparatus Just Yet

WE can supply you with high-grade apparatus that has been slightly used and discarded through no fault of its own, at an **immense saving in cost.** For instance, in many cases we take over entire plants simply because of changed conditions such as increased capacity, change of system, etc.

EVERYTHING IS OVERHAULED AND REFINISHED BY US AND **GUARANTEED** AS GOOD AS NEW, BOTH ELECTRICALLY AND MECHANICALLY.

Our catalogs of offerings should be in the hands of every power plant superintendent each time they are gotten out, and it will be worth while for anyone interested in this class of power plant equipment to be on our mailing list to receive all offerings.

Nearly all of the principal power, lighting and street railway plants in the United States are our customers.

Fifty Subscriptions from One Firm

THE International Business Machines Company, of which Mr. Frank E. Mutton is vice-president and general manager, subscribed to 10 copies of THE FINANCIAL POST some months ago—these copies to go to their travelling salesmen. Now this company has increased the number of these subscriptions to 50 because the results of the experimental subscriptions have proved so satisfactory.

FRANK E. MUTTON

Mr. Mutton explained that the object of putting THE POST in the hands of the men of his company was to keep them intelligently acquainted with general business conditions in Canada. He said he knew no better paper than THE POST for the purpose. It would seem that his men have responded fully to effort made to keep them well informed about Canadian business affairs—so much so that the management have added 40 other men to the original 10 to receive THE POST.

When Mr. Mutton was with the National Cash Register Company as its Canadian manager, he was the king of all managers in the matter of sales records. In this position he achieved a big reputation built on solid achievements. He learned salesmanship in a school where competition was of the hottest kind, and where the competitors were brilliant men. Giving Mr. Mutton full credit for superior personal qualities and energy of the most ardent kind, it is taking nothing away from him when it is said that not a little of his success was due to his intimate and sympathetic knowledge of the other man's business. And he taught the men associated with him as salesmen to know the point of view and requirements of the men they called on to sell machines to.

As vice-president and general manager of the International Business Machines Company, Mr. Mutton is putting into operation an idea used by him in past days with brilliant results—he is causing his salesmen to know the business and requirements of their prospective customers. To establish points of contact swiftly and surely is one of the open secrets of successful selling.

In the case of **your** solicitations of customers and desired customers, it is excellent strategy to have your salesmen so well informed about business conditions generally, and about the interests of the men they canvass, that they will be able almost instantly to relate their proposals to the interests of the buyer. When a salesman shows himself intimate with the interests or business or objectives of the man whose order he wants, he is immensely strengthened as a salesman, and his percentage of successful canvasses goes steadily up.

Our definite suggestion to you is: Subscribe to THE POST yourself, and learn from its pages how your salesmen or executives can draw power from this newspaper. Then, having acquired the sought-for knowledge, subscribe to THE POST for each man in your service who can profit you by knowing what is in THE POST each week. If Frank Mutton and other prominent executives are making a success of THE POST as a salesman's aid, it is reasonable to suppose that other managers of salesmen and executives can likewise employ THE POST as a producing agent. And so we ask you to sign and forward the coupon below.

The MacLean Publishing Company, Limited,
Dept. P.H., 143-153 University Ave., Toronto.

Send me THE FINANCIAL POST OF CANADA (weekly). Subscription price of $3 will be remitted on receipt of invoice in the usual way. Have this copy sent to

Even the Student Engineers Know

Turn loose a class of young mechanical engineers on an inspection trip in your plant, and one of the first places they head for is your boiler room. They know that the economical production of power is a fundamental requirement of modern successful industry, and they are keen to see where and how your steam is generated.

What an interest they take in every detail of equipment—draft regulation, stokers, etc. "There's Diamond Soot Blowers," one calls. Then what questions they put to the operating man. "Which of the units are calorized to prevent burning?" "So it is really true that there is a unit over the arch, which cleans all of the lower part of the first pass?" "Do you blow the tubes three times or four times a day?" "Have you accomplished more than a five per cent. fuel saving since installing the blowers?" "How much labor and overtime have you eliminated?"

One would think they had been taking a post-graduate course in Mechanical Soot Blowers. Nor would one be far wrong. All over the country the deans and professors of engineering schools are including instruction on the design, construction and operation of mechanical soot blowers in their power plant courses. The Diamond Company gladly contributes bulletins, illustrated lectures and moving pictures to this educational work.

If you don't want your own son, home from college, or the first young engineer you hire to exhibit superior knowledge of Diamond Soot Blowers, send for our Bulletin 160.

UEHLING WASTE METER

COMBINED

CO_2 AND TEMPERATURE RECORDER

Record of CO2 and stack temperature on one chart.

CO2 Indicator for Boiler Front

Does your fireman know how much fuel he is wasting? Do you know?

The **Uehling CO_2 Recorder** makes a complete 24 hr. record of your combustion efficiency and the **CO2 indicator at the Boiler Front** holds the fireman responsible.

Get more **Steam** per pound of **Coal** and reduce your annual fuel consumption.

Let us know the number and size of your boilers and coal consumed per year, upon receipt of which information we will be glad to send you full particulars.

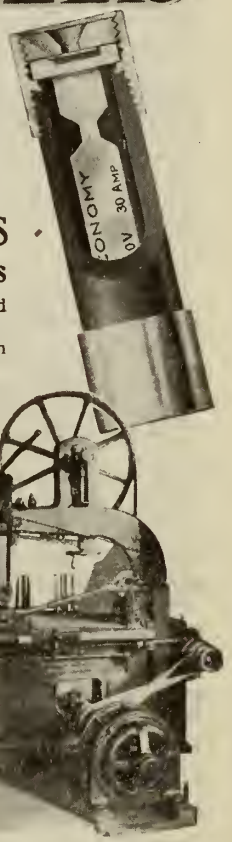
Let us hear from you. We are pioneers in the manufacture of Indicators and Recorders for Power Plant purposes.

Send for our Bulletin No. 110.

Uehling Instrument Company

2008 Empire Building New York City

THE TRAIL BLAZER



THE ECONOMY is the pioneer that opened up the renewable fuse field This is the fuse with the incomparable renewal element—the "Drop Out" Link.

ECONOMY Renewable FUSES and "Drop Out" Renewal Links

are used in thousands of plants, large and small, representing all branches of industry Their efficiency and economy have been proved over and over. They are uniformly accurate in rating. As compared with the use of one-time fuses they cut annual fuse maintenance costs 80%.

An inexpensive "Drop Out" Renewal Link restores a blown Economy Fuse to its original efficiency. It does away with the need of powdered filler. Even a novice can replace the link and renew the fuse in a moment.

MARSH and AMERICAN

Steam and Power Driven Pumps and Air Compressors

This book should be in the hands of every pump user. A postal will bring your copy promptly

Marsh and American Pumps are especially adapted for long, hard service because they are *extra heavy* in design and of *extremely rigid construction*. Every unit is built amply strong to withstand 24-hour-a-day service and to stand up under any unforeseen strain which may be placed upon it. Piston rods on the steam pumps are extra large and made of solid bronze. The water ends are equipped with heavy cast bronze removable bushings.

This superior construction not only insures continuous and satisfactory operation, but practically *eliminates expensive shut-downs*. Marsh and American Pumps are the product of over 25 years' experience in the design and construction of high grade pumping machinery. Over 135,000 in actual service throughout the world.

The AMERICAN-MARSH LINE OF CENTRIFUGAL PUMPS is composed of both single and double suction types which are designed for heads up to 125 feet. They are equipped with wide ring oiled bearings and the single suction type has overhanging casing enabling the discharge to be taken at any angle desired.

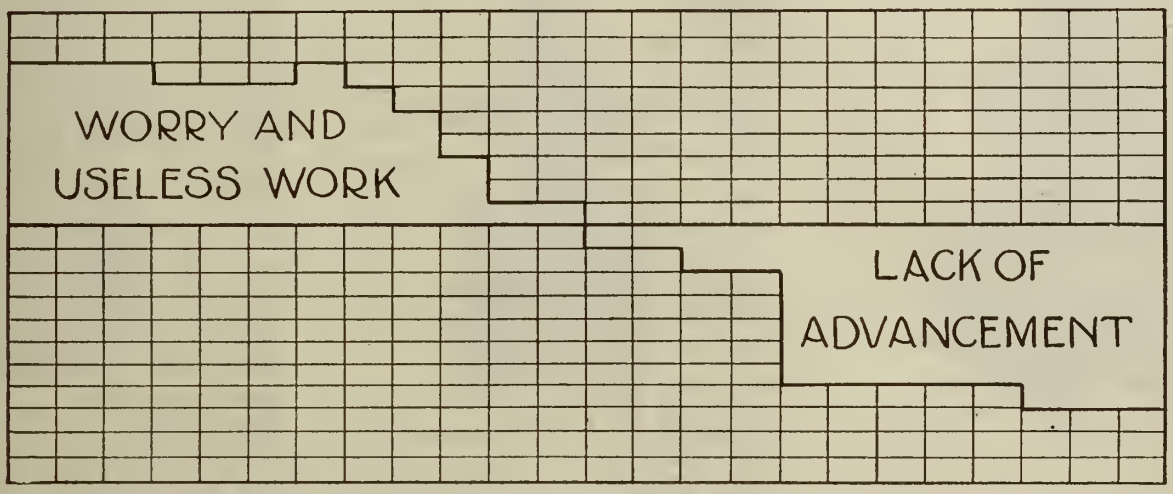
Let the C.A.S.E. Smooth Out Your Load Curve



Remove The Peaks of Worry And Unproductive Labor And Build Up The Valleys By Working For Your Advancement

A man who is thoroughly grounded in the practice of his profession, who is free from personal worry and trouble, overcomes the many difficulties besetting the path of the operating engineer with little labor and in a manner ensuring his advancement.

The successful man owes his success to a wise appreciation of the advantages and mutual help offered by association with those in the same field of endeavor. To join an association having for its objectives the welfare of the engineer in things mental and material, his advancement in knowledge and skill, his protection by provision for sickness and distress is to take advantage of an opportunity indispensable to all who hope to better themselves.

If you are interested in such an organization and live where less than fifteen engineers are located, send for a copy of our constitution and application blanks for admission to nearest branch lodge. If there are more than fifteen engineers in your community, get together and send for particulars regarding formation of a branch lodge.

J. H. HALE, General Secretary,

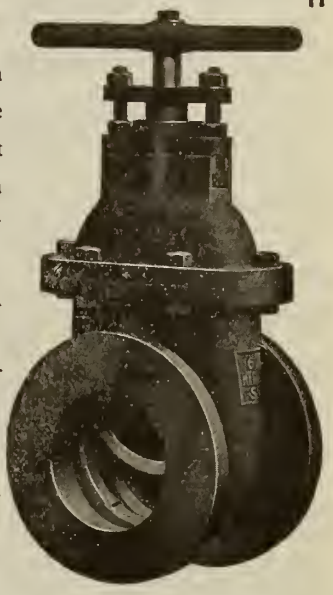
KERR
("New KEYSTONE" Pattern) GATE VALVES

If you have not used any of these New Pattern Valves, specify "KERR" in your next order. We want you to get acquainted with the most reliable valve on the market.

If you have been using them, we are confident that our satisfaction will bring us your repeat orders These valves will never cause you or your customer the slightes trouble. Their high quality is consistent.



When you buy a "KERR" Valve you get a guaranteed article that is backed by a reliable firm. Many of the largest distributers of valves in Canada have sold "KERR" Valves for over 25 years, and are still recommending them as the "Best Valve." Write us for particulars.

Kerr Engine Co., Ltd., Valve Specialists **Walkerville, Ont.**

Boiler Room Efficiency Instruments

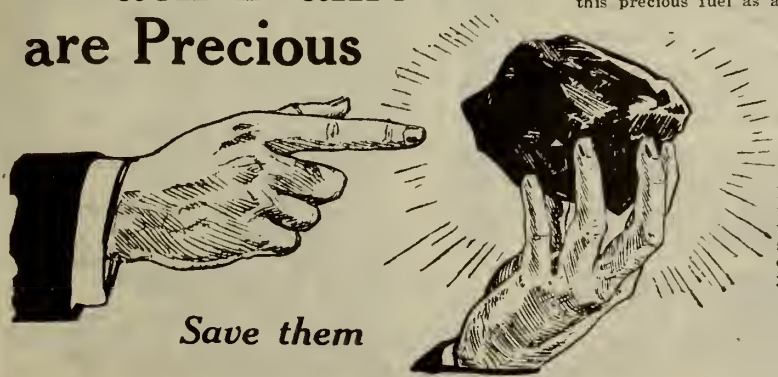
NO MORE GUESSING IN YOUR BOILER ROOM
THE DEFENDER SYSTEM (READS)

Draft, Temperature and CO_2 on each Boiler. Determine the Draft over the fire and at the last pass of the Boiler and the drop in Draft through the Boiler—that gives the highest percentage of CO_2 in the Flue Gas and the lowest Flue Gas Temperature.

This gives the highest Boiler and Furnace Efficiency. The Defender Catalogue No. 10, which is just off the press, shows a very complete line and price list of Combustion Appliances and Damper Regulators for the Boiler Room.

The Defender Automatic Regulator Co., 709 Pine St., St. Louis, Mo., U.S.A.

"Black Diamonds" are Precious



Save them

COAL is scarce. The supply is still limited. Scarcity means high prices. You should save every piece of this precious fuel as a measure of business economy.

Morehead Back-to-Boiler System will Save 8 to 20% of Your Fuel.

It keeps condensation out of your steam lines by returning it to the boilers while it is HOT. In a year's time you save many tons of coal. The MOREHEAD SYSTEM gives freedom from steam troubles and maintains a uniform temperature throughout the plant. Requires practically no attention. Let us tell you more about the New Improved Morehead Trap.

The Wrench of 25% Greater Efficiency

TRIMO PIPE WRENCH

Two new features have been recently added to the Trimo Pipe Wrench, namely Nut-Guards, in all sizes, and unbreakable steel frames, in leading sizes.

The Nut-Guards prevent the accidental rotation of the nut while in use.

These improvements add 25% to the usefulness of the tool.

The Trimo Pipe Wrench is made with wood handles in 4 sizes, 6-in., 8-in., 10-in., 14-in. and in steel handles in all sizes, 6-in. to 48-in. inclusive.

All Trimo Pipe Wrench parts are interchangeable.

The inserted jaw in the handle can be readily replaced when worn, thus adding to the life of the tool.

Nut with Nut-Guards

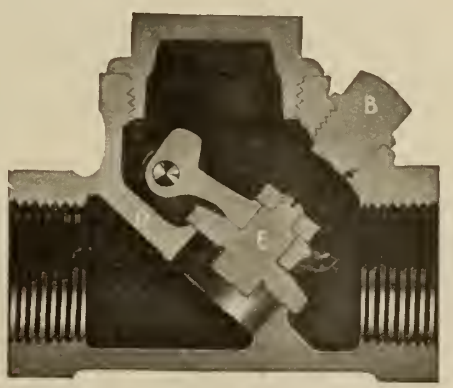
PENBERTHY

SWING CHECK VALVES

External View

There is nothing safer than a **Penberthy Double Plug, Regrinding Swing Check Valve.**
The "Check Superior," that overcomes **valve prejudice** on steam lines.
It can always be relied upon to work.



Sectional Side View

Penberthy Swing Check Valves are substantially and strongly made. Possess a special wear resistant bronze composition disc. Have a liberal thickness of metal in both body and diaphragm.

Note the double plug feature; a decided advantage over all other makes. Allows all repairs to be made without removing the valve from the pipe line.

All genuine **Penberthy Checks** bear our trade mark and the registered pressure 200 lbs. is cast on each.

The **Penberthy** name is in itself a **"guarantee of quality."** Engineers, Steam-fitters, Plumbers, Purchasing Agents know that.

Cash in on the **Penberthy Reputation** by stocking a line of **Penberthy Valves.**

Regrinding, Compodisk, Check and Gate Valves.

KEEP DOWN UP KEEP ~

STEADY dependable power is necessary if repair and up-keep costs are to be reduced to a minimum. Steady power means fewer repairs, not only on your engine or dynamo, but on all machines throughout the plant.

Without correct lubrication, steady power and an efficient power-plant is impossible. Scientifically and carefully made lubricants like those offered in the Imperial line will make your power-plant run smoothly, with the greatest possible efficiency and the minimum of care and attention.

Good mechanical engineers know this. They know too, that they will secure a uniform lubricant of high quality if they buy one of our well-known brands—a lubricant that will always give good satisfaction and better dollar-for-dollar value.

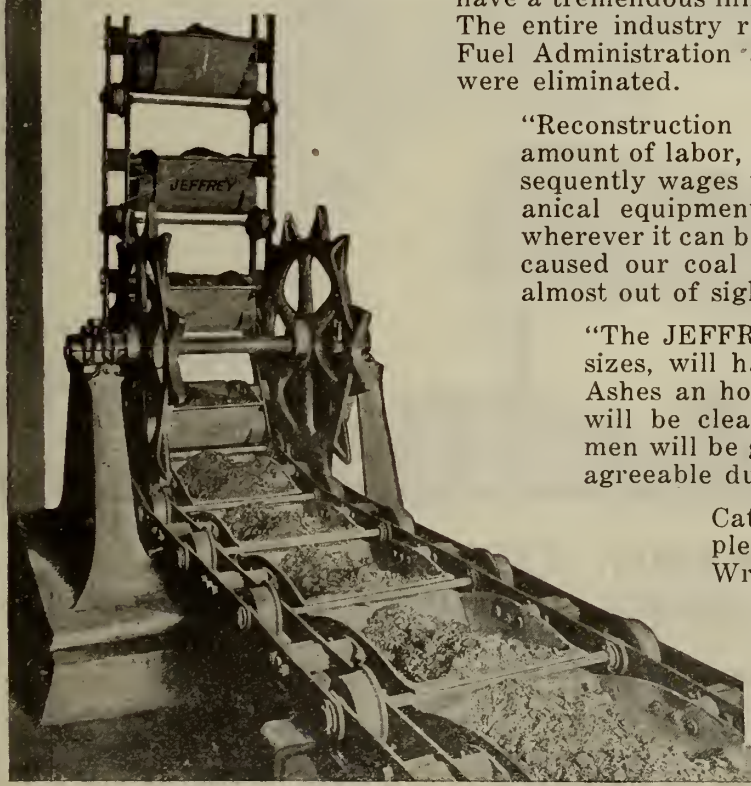
"Now That Federal Restrictions Are Removed We Will Extend the Plant and Install the JEFFREY Improved Carrier"



"The war and consequent Government supervision will have a tremendous influence on power plant operation. The entire industry readily fell in line with the U.S. Fuel Administration and many long-standing wastes were eliminated.

"Reconstruction activities will call for a vast amount of labor, both skilled and unskilled. Consequently wages will continue high, so that mechanical equipment will be far more economical wherever it can be applied. War-time wages have caused our coal and ash handlng costs to climb almost out of sight.

"The JEFFREY Carrier, which is built in six sizes, will handle 30 to 160 tons of Coal or Ashes an hour for far less costs. The plant will be cleaner and more efficient and the men will be glad to be released from this disagreeable duty."

Catalog No. 210-A describes completely the JEFFREY Carrier. Write TO-DAY for your copy.

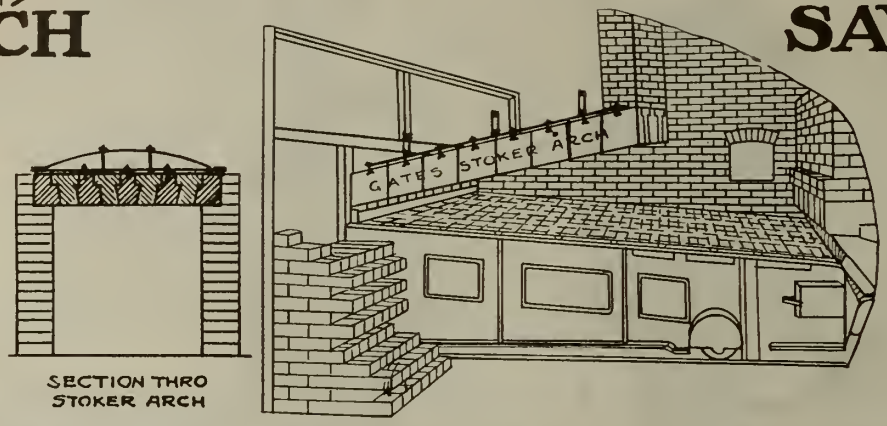
Handle it Mechanically

GATES STOKER ARCH

A MONEY SAVER



SECTION THRO STOKER ARCH

The greatest source of expense in connection with the operation of furnaces, is the destruction of the brick lining in the fire chamber. In many instances it is necessary to dismantle the entire brick work in order to make the necessary repairs. In addition to the cost involved, this method frequently requires the shutting down of the furnace for several days. This objectionable feature has often resulted in a furnace being operated much longer than it otherwise would, the consequences being the complete destruction of the brick lining.

The "Gates" Stoker Arch is built to minimize these disadvantages and at the same time effect a saving in the cost of maintenance.

Our new type of arch block is adapted to Dutch oven type of boiler setting, or H.R.T. boiler back arches, large fire door arches, reverberatory and smelting furnaces as well as stoker arches.
HERE'S A BIG ADVANTAGE—Being built on the unit principle any section of the arch can be replaced without disturbing the rest of the brick work.
If your setting is not standard we will design a block to suit your requirements.

We Specialize in all kinds of POWER PLANT BRICK WORK.

CALL ON OUR ENGINEERS AT ANY TIME FOR INFORMATION YOU MAY REQUIRE. THEIR SERVICES ARE OFFERED TO YOU WITHOUT OBLIGATION.

TALBOT
Contra-Flow Steam Boilers

(Equipped with Crude Oil Burners)

The "Talbot" is a boiler of the contra-flow type, water entering near the stack and leaving in the form of steam near the furnace.

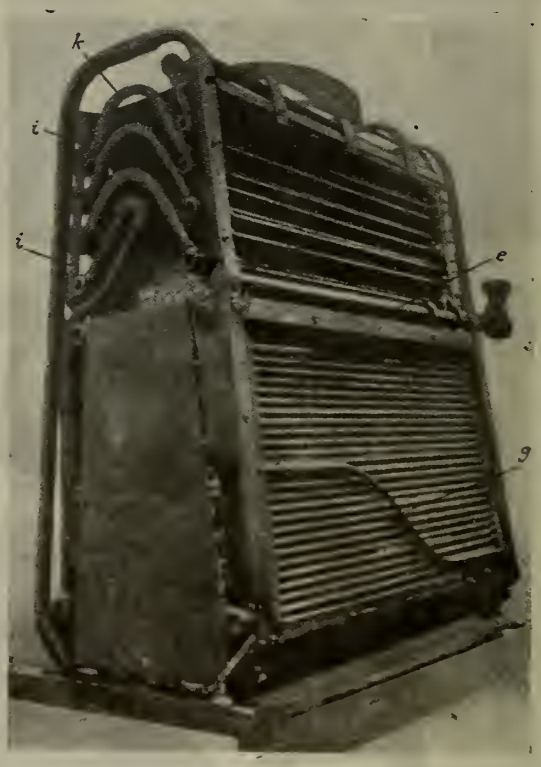
Cost of operation is cheaper than any known power producer.

The circulation is through water tubes and is forced at a high velocity by means of a pump, doing away with a water drum. By preventing gravity circulation the steam is drawn directly from the lower tubes, eliminating the steam drum. The boiler is internally fired, and hence self-contained. Feed water and fuel burners are automatically controlled to adjust the boiler to widely varying demands for steam.

For full particulars write.

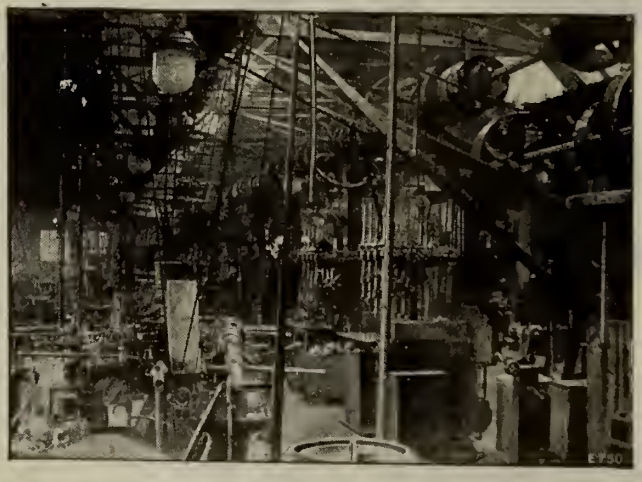
Canadian Manufacturers and Sales Office:

Montreal General Tool Co., Ltd.
675 Notre Dame, Maisonneuve
MONTREAL, P.Q.



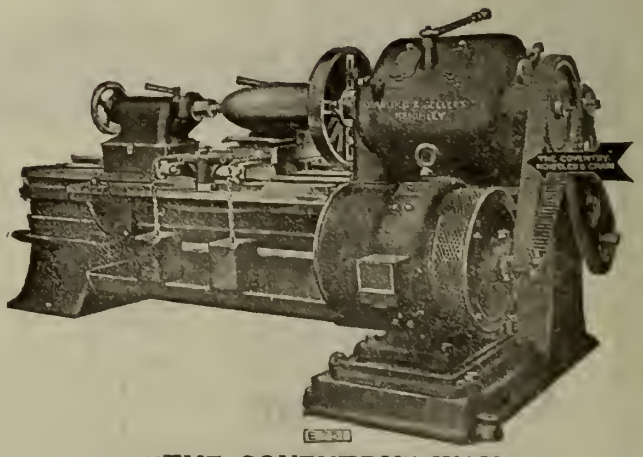
Head of Boiler Casing Removed.

Requires about one-seventh the space of the ordinary boiler.
No brickwork is necessary.
Tubes easily replaced under reduced steam pressure.



THE OLD WAY

Notice the space occupied by belts, pulleys and shafting, which darken the workshop and throw shadows on the work.



"THE COVENTRY" WAY

A bright factory means improved work and larger output, less likelihood of accidents. (Note compact arrangement of drive).

Outside

Protection for Pneumatic Tool Hose

—an outer jacket that ensures longer service and big economies.

HOSE that ensures longer service and big economies.

Pneumatic tool hose is important enough to deserve our preferred attention—and yours.

So we studied pneumatic tool hose performance to develop a hose that would give longer and better service; that would make the specifying of this hose matter of importance to you.

Goodyear Extra Service Pneumatic Tool Hose was the result—a hose that is doubly protected.

The inner tube is made of specially prepared rubber to resist air pressure effectively. Even after long use this hose remains elastic, active, unified.

The smooth white cover is made of extra tough rubber—rubber as tough as the tread of a tire. No wire winding — easily handled, and light in weight. Rough usage, knocks, abrasion — the things that make ordinary pneumatic tool hose a steady item of expense—are slow to impair the efficiency of Goodyear Extra Service Pneumatic Tool Hose.

Its different and better construction insures longer service and real economy.

A hose purchase may come up in your concern any day. Write or telephone the nearest Goodyear branch for a hose man to call with samples. No obligation—you are not expected to order. We just want you to know all about this **better** hose when you need hose.

PNEUMATIC TOOL HOSE

The Publisher's Page

TORONTO APRIL 25, 1919

"The Best Paper of Its Class"

POWER HOUSE is now safely launched on its semi-monthly journey, and from every part of the Dominion there are coming many letters of commendation and assurance. Here is one example:—

Donavon, Sask., March 5, 1919

Dear Sirs:

In answer to your inquiries re "Power House," I certainly am in favor of a semi-monthly publication of this paper. In my opinion it cannot be published too often.

As far as the subscription rate is concerned I shall continue to take "Power House" whatever it costs.

I might say that I have been several times around the world as an engineer in the British Merchant Service and it is the best paper of its class I have ever met.

I would very much like to see marine work discussed occasionally. Other than that I fail to see where "Power House" can be improved.

Believe me,

Yours truly,

PERCY S. HUNTER.

The editorial and advertising pages of POWER HOUSE are equally appreciated by the readers—this is clearly shown. Engineers have said: "I find the advertisements valuable to me, the information about the merits of the machines is interesting." POWER HOUSE, because of its stand for the upbuilding of efficiency in power plant equipment and service, quite naturally attracts owners, superintendents and the best engineers. It is a medium recognized as possessing leadership. It maintains a strong influence on those who direct the buying of power plant equipment. It is the one sure medium of publicity for the manufacturer.

THE VALUE OF MASON SERVICE

WE are prepared to supply the Engineering Equipment mentioned below and would further point out that we have a large experience in the practical application of our engineering equipment to actual service conditions. Our salesmen are practical engineers and sell from knowledge not from catalogue. Their suggestions are usually useful.

This is Mason Service.

THE MASON LINE INCLUDES:—

"Mason" Reducing" Valves (genuine).
"Mason" Pump Governors.
"Mason" Pressure Controllers.
Bundy Steam Traps for every service.
Coppus Turbine-driven Blowers.
Coppus Turbine-driven Boiler Feed Pumps.
Sims Hot Water Generators.
Sims Storage Heaters.
Sims Open Feed Water Heaters.
Bundy Oil Separators.
Ashton Gauges and Safety Valves.
Everlasting Blow-off Valves.
Babbitt Sprocket Rims.
Stratton Steam Separators.
Reilly Feed Water Heaters.
Reilly Evaporators and Distillers.
Reilly Feed Water Filters.

The Safe and Certain Boiler Cleanser

Anti-Clinker Shell Bar Grates

There's no coal waste where these grates are used. Maximum air-space provides for perfect combustion. No clinker formation here, and you get more heat with less fuel.

One-Piece Jointless Furnace Lining

Why shift the blame on your engineer or fireman when it is your furnaces that are not up to the highest point of efficiency? USE PLIBRICO—it lasts longer than fire brick and is easier to install.

Tip-It Patent Welding Process

With TIP-IT you get tools with shanks of carbon and tips of high-speed steel.

PUT a barrel of BOICO in your boiler room. It's the most efficient and economical **clean-boiler insurance** you can adopt. BOICO routs the most stubborn cases of boiler scale formations quickly and thoroughly.

Hundreds of Plants are Using BOICO Every Day With Unqualified Success

What BOICO will do in one plant it will do in another—**it will do in yours.**
BOICO loosens and brings away the hardest of old formations and keeps new scale from gathering. Yet it never does the slightest injury to boilers, valves or packings. Neither does it carry over in the steam, nor cause foaming or priming.

We are confident that BOICO will live up to all our claims and are prepared to let you test it FREE of cost. You have nothing to lose by trying it—let us hear from you.

O.K. for Time and Labor Saving in Any Plant

Steam Trap Losses

Should Be Classed as Unnecessary

Steam trap losses contribute largely each year to plant operating cost. In terms of lost time, too frequent adjustments, blowing off, steam leakage, they represent repeated waste. These have been entirely eliminated—and time losses changed into steam savings—where the Johns-Manville Steam Trap is used.

This trap has but three parts—a body, bushing, and hollow ball. When there is no condensate to discharge, steam pressure in the trap holds the ball against the discharge orifice—the only point where there's unbalanced steam pressure. As water flows into the trap, the ball is rolled up, the unobstructed orifice is exposed, and water is discharged. This discharge is continuous as long as water flows to the trap. If air is present it is drawn out through vortices formed at the discharge orifice.

There are no levers, counterweights, springs, or other "fixin's." It is the most simple and efficient trap made, and absolutely tamper proof. Ask our nearest branch for special bulletin—it can solve your trap troubles.

What They Say About Power House

"I certainly am in favor of a semi-monthly publication. In my opinion it cannot be published too often. I have been several times around the world as an engineer in the British Merchant Service and POWER HOUSE is the best paper of its class I have ever met."—Mr. Percy S. Hunter, Donavon, Sask.

"I would like very much to get POWER HOUSE twice a month. For Canadian engineers it is unexcelled."—Mr. A. R. Troke, Paris, Ont.

"New subscribers who do not really know the value of POWER HOUSE might demur at paying a high price for it, but personally speaking, I would not object to paying double price for double service. I never miss reading the advertisements. They are real interesting to anyone in this line."—Mr. Fred E. Reesar, Municipal Electric Light Plant, Markham, Ont.

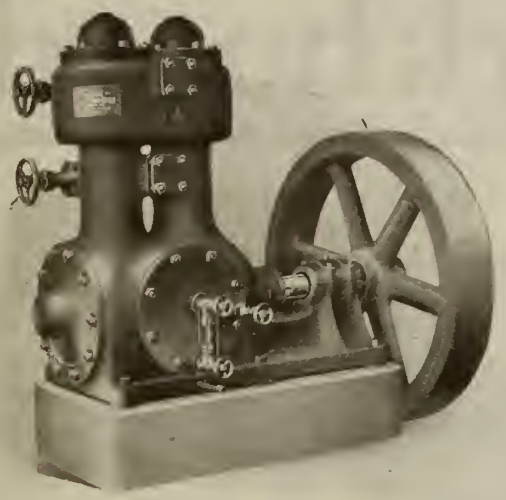
"I feel that a semi-monthly magazine will also be a great step in our favor inasmuch as we can now look forward to a friend and adviser's call twice a month instead of once. I take a number of magazines myself, but there is none I look forward to receiving like my old friend and adviser, POWER HOUSE."—Mr. L. E. Wight, Drumheller, Alberta.

"I favor the change to semi-monthly. It is worth twice the money to a Canadian engineer when compared to other magazines published in the U.S.A., upon which I am basing this suggestion."—Mr. Fred R. McNeil, Shawinigan Falls, Q.

"I am very pleased to hear that POWER HOUSE is to be published twice a month as I have been a reader of it for several years. The change will be a great help to engineers."—Mr. W. E. Dale, Vancouver, B.C.

and Hundreds More Say the Same

Quality Products Leave No Regrets



York Ice-making and Refrigerating Machinery is not made to fit the price. We have a standard of quality and service which has been maintained ever since the York Organization was started.

It is betraying no secret to say that many owners of ice-making and refrigerating plants have expressed to us, by word and letter, their keen regret at having turned down a York contract because the price seemed too high.

Price is a poor gage to use in buying such important equipment as Ice-Making and Refrigerating Machinery. Confidence is a better one. You know from your own experience that business born of confidence begets new business.

No customer can truthfully say that the York Organization ever tried to take advantage of him. It is on this basis that we have been selling our products, and it is for this reason that we have been successful.

An inquiry from you will be appreciated. You are not obligated to buy York equipment until you are satisfied as to its quality and our good intentions.

Temptations

In these days of high prices, the temptation is often strong to put off repairs and improvements until the last minute, and then try to save money by purchasing materials cheaper in first cost but of doubtful efficiency. Either policy is liable to prove disappointing and costly in the end.

The time to get ready for next season's business is not when the hot weather is upon you, but right now when the load on your cold storage rooms is light. The sooner you make your repairs and improvements, the better. Materials are scarce and transportation is very uncertain at best.

And nowadays the best is still the cheapest. You can get cold storage insulating materials that will be cheaper than Nonpareil Corkboard in first cost, but in the long run—after they have become moisture-soaked, worthless as heat-insulators and have to be replaced—they are many times more expensive.

Fruit storage room insulated with Nonpareil Corkboard, Altschul Bros. Company, Lima, Ohio.

If you are not already familiar with it, there are many facts about Nonpareil Corkboard Insulation that will interest you as a business man. The 152 page, illustrated book and samples of the materials will be sent, free of charge, on request.

Armstrong Cork & Insulation Co., Limited

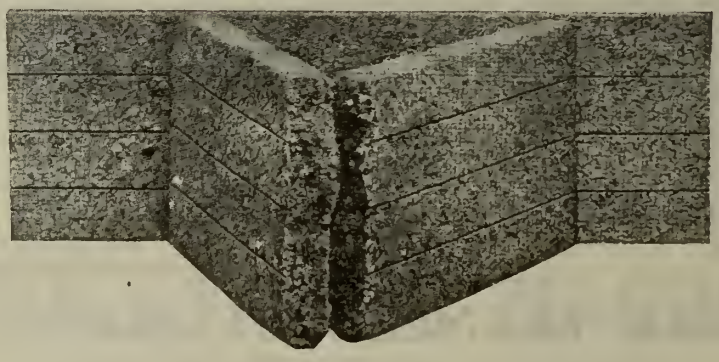
Pure Corkboard

Made in Canada



A New and Important Source of Supply

All buyers know that the sources of supply of pure Compressed Corkboard and Granulated Cork are few—too few —and the output entirely inadequate at times—an unhealthy situation for the buyers.

Therefore, you have special interest in this *new* and *important source of supply,* large in volume, fine in quality and right in price.

It offers you added *security* both as to *cost* and *deliveries.*

Pure Corkboard is now a necessity to the refrigerating industries, which use many millions of square feet yearly in the insulation of more than eighty per cent. of new construction and repair work.

We are prepared to handle your complete requirements, either for material only or installed in your building. Write us to-day and we will gladly give you full information and quotations.

What Is Your Repair Bill?

Did you ever stop to figure up how much your present feed pump is costing you per year? Do you realize that there is a pump which can cut down your cost of boiler feeding?

The ordinary boiler feed pump constantly needs expensive repairs—and is always giving trouble on account of leaky valves and pistons. With the

COPPUS TURBO FEED PUMP

there is no steam leakage—because there are no valves. With a COPPUS Turbo Feed Pump repairs are negligible—because there are few moving parts. In a COPPUS Centrifugal Turbo Feed Pump the depreciation is unusually low—because there is practically nothing to wear out except ball bearings and wearing rings.

Then, too, the COPPUS Turbo Feed Pump is very economical in steam consumption, and absolutely automatic in regulation. A self-oiling system and an excess pressure regulator minimizes the attention required.

These are some of the reasons why the COPPUS Turbo Feed Pump is rapidly becoming the choice of efficient engineers everywhere. Write for Pump Catalog H5, and let us show you how "COPPUS equipment can save you money."

Dominion Belting Company, Limited
Hamilton, Canada

Sole manufacturers of the celebrated "MAPLE LEAF" Brand Stitched Cotton Duck Belting and Belt Dressing.

The demand for our products has steadily increased because the standard of quality has been maintained.

We make only one grade, the best that can be produced.

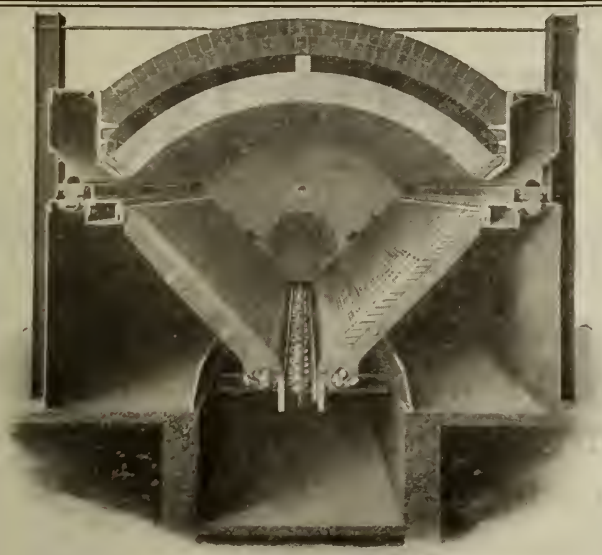
"MAPLE LEAF" is the strongest, truest running, most economical and efficient belt on the market for transmission of power, conveying, etc.

Being thoroughly waterproof it is suitable for running in wet or dry places. **"MAPLE LEAF"** Belt Dressing is different to others offered in that it is equally good for all kinds of belting, leather, rubber or Balata, as well as our own make.

Write us for prices, and if desired we will be pleased to furnish samples and further information.

A trial order will convince you of their utility.

DOMINION BELTING CO. Ltd., Hamilton, Canada-Quebec Branch: 51 Duluth Bldg., Montreal



Sectional View of Murphy Automatic Furnace

The Murphy Furnace is designed to extract the utmost energy out of fuel, efficiently and smokelessly, with minimum attention of the operator.

While, of course, bituminous coal produces the most economical results, the Murphy Furnace, however, will burn such fuel as slack, lignite, sawdust or even refuse efficiently enough to keep a plant operating during emergency. The construction of

MURPHY AUTOMATIC FURNACES

is such that they feed the fire from two sides (not one) giving double the coking area. The coal is fed—the fire cleaned—the ash discharged—continuously and automatically.

Boilers fired by Murphy Furnaces do not require auxiliary forced draft (a large initial saving). The excellent air distribution—57% air space—makes the stoker exceedingly efficient and gives the power plant that true form of economy which comes only through continuous automatic operation.

The Murphy operated plant can truthfully say that they obtain all the necessary steam—with plenty of reserve capacity—without "one penny for draft."

You will be surprised to know how easily the Murphy Furnace can be installed under any type of boiler from 50 horsepower up. Our catalog HM-4 gives you details. Send for copy to-day.

For information on Riley Underfeed Stokers for large boilers, see last month's advertisement—or send for Riley Stoker Catalog HR-4.

POWER HOUSE

Established 1907 Published Semi-monthly

The Toronto Plant of The Wm. Davies Co.

Recent Extensions Result in Greatly Increased Capacity. Up-to-date Ice Plant a Feature of the Plant Design.

By W. F. SUTHERLAND
Editor POWER HOUSE.

CANADIAN industries were a material factor in the supplying of munitions to the Allies and of equal importance has been the part payed in the provisioning of not only the armies but the people of the allied nations. The export trade thus built up necessitated large addition to the cold storage warehouses and equipment of practically every firm dealing in meat products. The extensions recently completed by the William Davies Co. have involved rather extensive alterations to certain portions of the Toronto plant, and have necessitated the addition of much new equipment. New loading docks and car icing platforms have been built, and a new cold storage warehouse constructed; this latter also houses a meat market for city trade. Together with these changes new refrigerating machinery has been installed. The old and new units of the mechanical equipment form the basis of this article, the various cooling rooms and warehouses being treated in a future article.

Absorption Plant

The absorption system, which forms the older portion of the equipment, is of much interest not only on account of its being one of the few in Canada, but also on account of the length of time which it has been in service. Three units are installed, all made by the Carbondale Machine Co., Carbondale, Pa. The 40 and 75 ton sets were installed in 1890, 29 years ago, while the 100 ton set is 8 years old, having been installed in 1911. These three absorption units have been in amost continuous operation since their installation, allowance being made of course for the lighter winter requirements of the plant.

The generators are of the horizontal type and are supplied with live steam from the boilers. The analyzers and exchangers are placed vertically above the generators, while the rectifier is placed outside. The condenser absorbers and brine coolers are on the main floor level, alongside the generators of each set. This system is very economical in operation, as the cooling water required is raised to about 90 degrees F., while passing through the condenser, and thus admirably serves for washing hogs. The condensate from the generators is returned to the boilers by means of Cole return traps. In passing it may be mentioned that all hot water returns from cooking, rendering and other plant pro-

ABSORPTION PLANT; THREE UNITS ARE SHOWN.

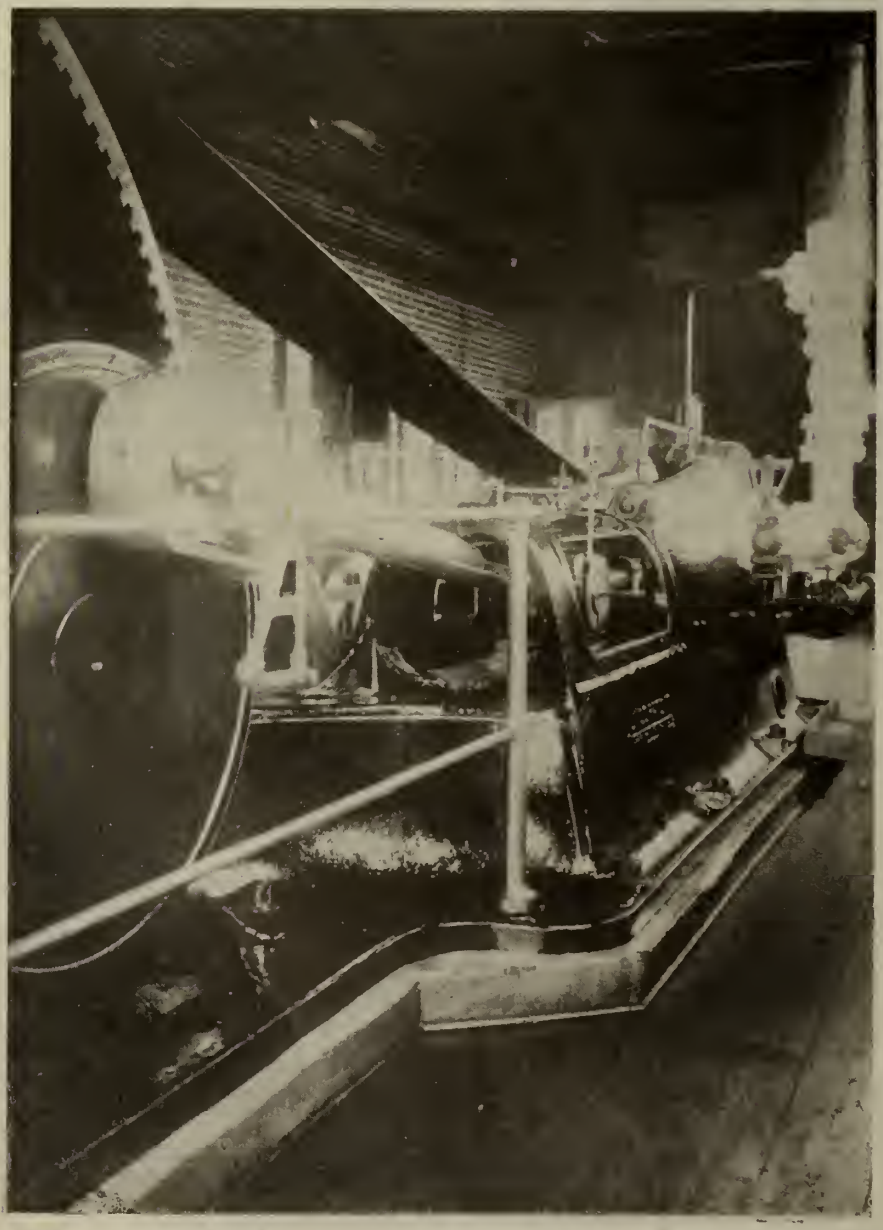
cesses as well as from the heating system are returned to the boilers by means of these traps, fourteen in all being used.

The ammonia pumps, which are the only moving part of this system, are all belt driven from a line shaft and are so arranged that any pump can be operated on any one of the three units.

The brine from the brine coolers is circulated by means of two Deane pumps, one for the low temperature brine, and one for the high temperature brine.

The low temperature brine is kept at about 10 degrees and is used for freezing, while the high temperature brine for chilling is circulated at about 15 degrees F. These pumps have also seen a good many years' service, sixteen and fifteen years respectively. Coupled with the power driven pumps are two booster pumps of 250 gallon capacity each; these pumps are of the duplex steam type of Martin make. They serve to provide a means of controlling the circulation of brine and also act as

CAR ICING DOCK.



LINDE COMPRESSOR IN ICE MACHINE PLANT

auxiliaries in the case of failure of the power driven pumps. In addition to this equipment another 500 gallon Martin pump is also installed for emergency uses.

Other Stand-by Equipment

Since power is now purchased from central station supply the old steam equipment is now little used, but fills a valuable place as stand-by equipment in the event of power failure. In the supply of power to the engine room equipment a Doty engine is used when needed. This engine is of 75 h.p., of the Corliss type and has been in service fifteen years. A Goldie & McCullough Ideal engine of 50 h.p. is also installed and is direct connected to a C.G.E. 110 volt generator for the supplying of the lighting requirements when needed.

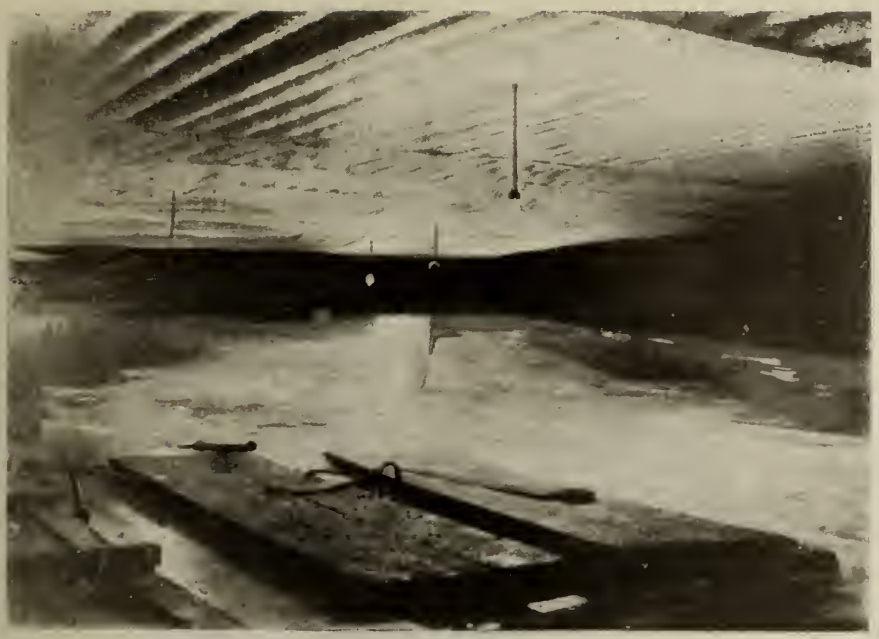
The power required for various uses around the power plant, such as the operation of the brine and ammonia pumps on the absorption system, is ordinarily supplied by a 50 h.p. Lancashire motor, belted to the line shaft. In passing is may be mentioned that this type of motor is used almost entirely throughout the plant.

Compression System

In the older portion of the plant, which has been dealt with up to the present, a Linde Canadian compression system is also installed. This system has a capacity of 125 tons of refrigeration per 24 hours. The Linde compressor is driven by a 175 h.p. Lancashire motor by means of a 28 inch Beardmore belt. As will be noticed in the accompanying illustration the motor has been placed on a concrete foundation some distance above floor level. This has been done since the Don River overflows its banks with unpleasant results so far as electrical equipment is concerned.

Boiler Room

The boiler room of a packing house supplies steam almost entirely for various processes carried on in the dressing



ICE STORAGE ROOM; NEARLY FULL.

and cooking of meats. Steam for power generation is in this case not required except as a stand-by service. Three Erie City boilers are installed, one of 500 h.p., and the other two of 330 h.p. each. Detroit stokers are fitted to each and the coal is conveyed to the furnace hoppers by means of a Jeffery bucket conveyor system.

The feed water is heated in a Cochrane heater and its supply is controlled by means of McDonough feed water regulators.

The Ice Plant

In the packing business much depends upon the proper care of the dressed meats when loaded for shipment. The modern refrigerator car, which plays such an important part in the shipment of perishable goods, needs ice in large quantities for its proper functioning, and the artificial ice plant is a necessary part of every packing house. The ice plant of the William Davies Co. forms part of the extensions recently completed and is a self-contained unit in every way.

The compressor illustrated in one of the accompanying illustrations is a Linde Canadian machine of 125 ton refrigerating capacity. It is driven by a 200 h. p. Lancashire 3 phase, 25 cycle motor by means of a 28 inch Beardmore belt. In addition to the making of raw water ice it also serves to cool part of the cold storage warehouse recently erected. A production of 56 tons of ice per day has been maintained in addition to the cooling of a portion of the storage warehouse and meat market.

The raw water ice plant is served by a Curtis pneumatic ice crane, the cakes being placed in the hot water stripping tank, after which the cakes of ice are hoisted either into the ice storage or are conveyed directly to the car icing platforms shown. The ice storage room has a capacity of approximately 3,000 tons, and is insulated by means of Armstrong cork, a nine inch thickness being used.

Provision has been made for ice crushing and salting equipment together with an overhead carrier system for ice buckets.

MOTOR DRIVE IN ICE PLANT

BOILER ROOM

THE SHORT BELT DRIVE FOR AIR COMPRESSORS

COMPRESSED air is a necessity in most plants. In the machine shop the air chuck is becoming more and more common, air hoists are used for heavy work in the machine shop and the foundry, and in the yard. In the majority of plants that use compressed air the installation of the compressor is usually a problem. In many plants the air compressor has to be squeezed somehow into an existing power-house where space is at a premium, and the question of the compact air compressor becomes very acute.

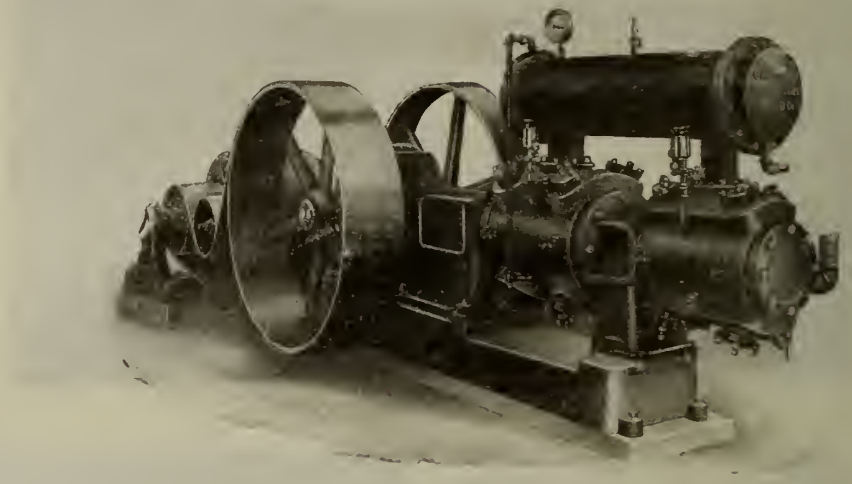
The steam-driven compressor by the very nature of its construction takes up very little room, but the steam driven type is not so common nowadays, and is usually found where steam is already generated for some other purpose. Now the ordinary belt drive for any type of machine takes up quite a floor space, and the compressor 8 feet long needs almost three times its own length for the ordinary belt drive. For the larger sizes the drive by direct-connected motor solves the space problem, but this form of drive is best suited to compressors large enough to require a motor of 100 H. P. or more, so that the direct driven compressor is not much help to the man who wants to get a small compressor into a corner "two by twice."

The short-belt drive solves the problem for him. The principle of the short-belt drive is best explained by a reference to the illustration; it consists simply of a light idler pulley riding on the belt between the compressor and the motor. But there is an important difference between the idler pulley of the short-belt drive and the ordinary idler; in the short-belt drive the idler is carried on arms mounted on the compressor frame, these arms are free to move up and down to a limited extent. Now the objection which at once leaps to the mind is that this idler pulley will increase friction to such an extent that other benefits will be of little use. However this objection is not so formidable as it looks. If the idler were rigidly fixed the friction would be objectionable, but it is not fixed, and the very slight added friction does not weigh against the advantages of the drive. So much is this the case that at least one large short-belt drive is required for large mill power transmission of all descriptions.

As to the advantages:—in the first place the short-belt drive saves space; a 10 x 8 inch Canadian Ingersoll-Rand EL-1 air compressor with short-belt drive takes up only 11 ft., 0 in x 3 ft., 0 in.—belt, motor, and all. The outlay on belting is reduced, and the increased contact angle on belt wheel and pulley adds a good deal more to the efficiency of the drive than is lost in idler friction. Lastly the belt needs no extra initial tension—many a good belt has been stretched too much for its first run;—and the idler automatically looks after tension.

Where compressors are concerned both chain and gear drive are not only very expensive, but they are too rigid, and consequently wear quickly, so that they are not very serious competitors of the short-belt drive—and the short-belt drive is noiseless.

In the installation care should be taken to follow carefully the maker's instructions regarding alignment. The correct location for the idler is just where it would be in the sag of the belt if there were no arm to restrain it. The belt should be slack enough so that it will wrap around the small pulley at least 180 degrees and preferably more usually made up endless by the manufacturer and given a special treatment to make it pliable for this service. With this type of drive it is considered advisable to use belt dressing very sparingly.



SHORT BELT DRIVE

SHORT BELT DRIVE

In gauging the setting of an expansion valve in starting up a refrigerating system, remember that a short coil in a cold room will evaporate very little liquid, while a long coil in a hot room will evaporate quite a large amount. If the suction pressure remains the same and the room or brine temperature goes up, the expansion valve must be opened more, and if the temperature goes down and the suction remains the same, or nearly so, the expansion valve must be pinched back a little.

* * *

Never use any more oil for an ammonia compressor than is absolutely necessary. If it is a horizontal machine and oil is supplied to the lantern in the middle of the stuffing box that is all that is required. Enough will leak through the packing and be carried into the cylinder with the rod to keep the cylinder sufficiently lubricated. About a quart every 24 hours supplied to the lantern will be plenty for a 100-ton machine. Very small machines will require a little less and larger machines a little more. Ammonia itself is slightly lubricating, especially if a little liquid is carried back with the gas.

* * *

The proper condenser pressure in an ammonia compression system is largely determined by the temperature of the condenser water, the size of the condenser, and the amount of water available. If the condenser is kept clean and free from oil on the inside, and scale on the outside of an atmospheric condenser, or the inside of the water pipes of a double-pipe condenser, and the condenser is large enough for the work and kept free from air, the condenser pressure should be such that the corresponding temperature of the saturated gas will be from 10 to 15 degrees higher than the condenser water supplied to the condenser. For example if the temperature of the cooling water is 60 degrees the temperature of the ammonia gas in the greater part of the condenser should not be above 75 degrees at the highest, which would correspond to a pressure of about 126 pounds.

The Selection and Care of Ammonia Compressors

Points to be Remembered When Choosing Machines, and Information of Value Regarding Their Operation

By J. F. PATTON

THE success of any mechanical refrigerating plant depends upon the ammonia compressor. It is the heart of the system and too much care cannot be given to its selection. Many types are on the market, each having its advantages and disadvantages, and before a selection is made, a competent engineer should be consulted as the questions involved are decidedly technical in their nature.

It is, however, very easy to decide

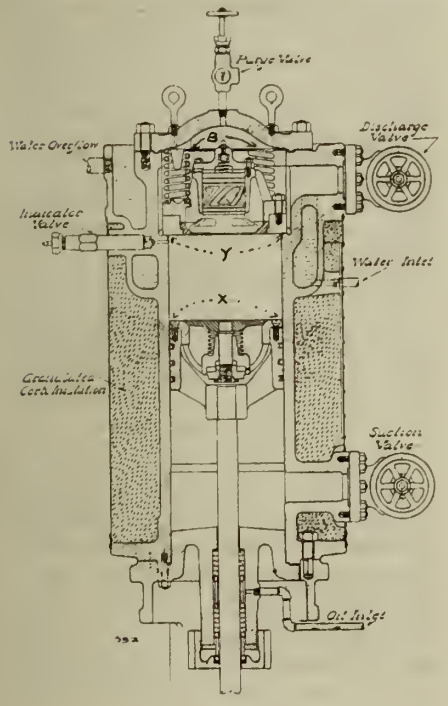


FIG. 1.

that the construction should be, 1st, of very substantial design so that occasional severe strains or overloads will not result in breakage; 2nd, that the piston should be as light as is consistent with safety and should fit the cylinder and valve seats as closely as possible; 3rd, the stuffing box arrangement must absolutely prevent ammonia leakage under any and all conditions, and should be designed to facilitate adjustment when starting and stopping; 4th, the suction and discharge valves must respond instantly to the pressures to which they are subjected and must be so arranged that it is not possible for a valve to fall into the cylinder in case of accident; 5th, all working parts must be accessible and easily adjusted, in no case requiring dangerous work on the part of the operator; 6th, all bearings must be of ample area so that ease of operation and proper alignment may be attained without excessive heating; 7th, design should permit handling either dry or saturated gas.

Compressors are classed as vertical or horizontal, single or double acting. It may be noted that the vertical type requires only a little more than half the floor space required by the horizontal; the weight of piston and moving parts in the cylinder is well balanced, thus guaranteeing uniform wear on cylinder walls; clearance may be slight because wear is all downward and the valves may be kept tight very easily because they seat in a horizontal plane.

On the other hand, a horizontal machine requires less head room than the vertical, usually has less moving parts, which reduces friction and liability to accidents, and all parts are located near the floor line which results in easy operation, as all strains are resisted by the supporting foundation, and as the engineer has no steps to climb, it is likely that the machine will receive better attention than would one of the vertical type. Finally, the horizontal type will perform equally well with wet or dry gas and its construction permits the use of a straight crank shaft which is not so likely to break as with one or more offsets.

Fig. 1 shows a sectional view of the York, a vertical, single acting compressor, with a false or safety head. The gas enters at the bottom of the compressor and passes up through the balanced suction valve in the piston, is compressed on the upward stroke to the condensing pressure and passes out through the discharge valve in the centre of the safety head. The piston and the bottom of the safety head are faced off square and as they come in contact, a complete discharge of gas is effected.

The use of the safety head guarantees against the breaking of the compressor in case of damaged valves, as it lifts and allows the obstruction to pass through or keeps on lifting until it attracts the attention of the operator, when the machine may be shut down without damage as would be the case if solid heads were used. In the case of an overcharge of liquid ammonia, there is a hammering

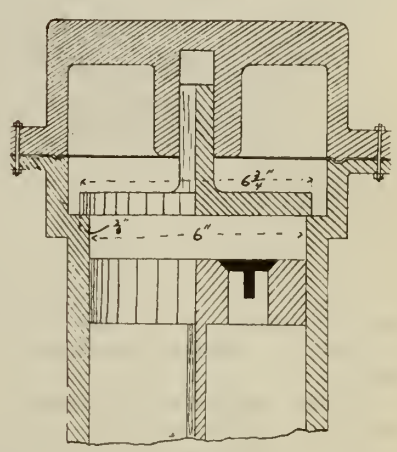

FIG. 2.

of valves and false heads as they rise to allow the liquid to pass.

In a machine of this type it is imperative that the screws shown at X Fig. 1, be absolutely tight. These hold the suction valve in position and frequently they will back out slightly or they may become battered so as to be useless as well as dangerous.

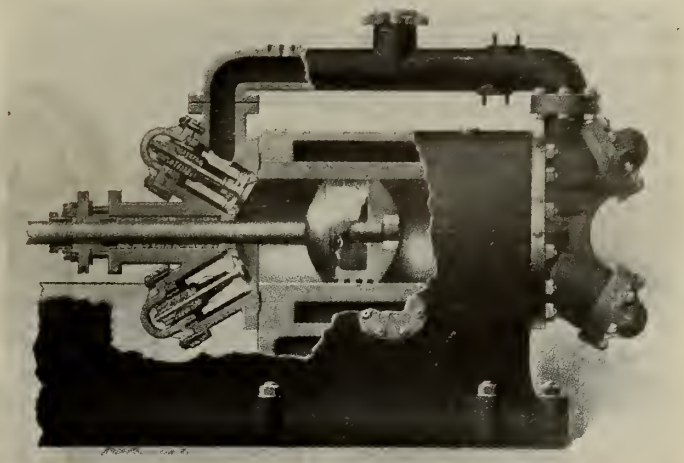

FIG. 3.

It is also necessary that the head and seat at Y make a good, pressure tight joint. This should always be tested on an over-

haul, a good method being to wipe the seat dry, mark each surface with a soft pencil, and rotate the head a few times. If the marks are not obliterated, the head must be ground in.

The springs as shown at B must also be kept tight as these hold the safety

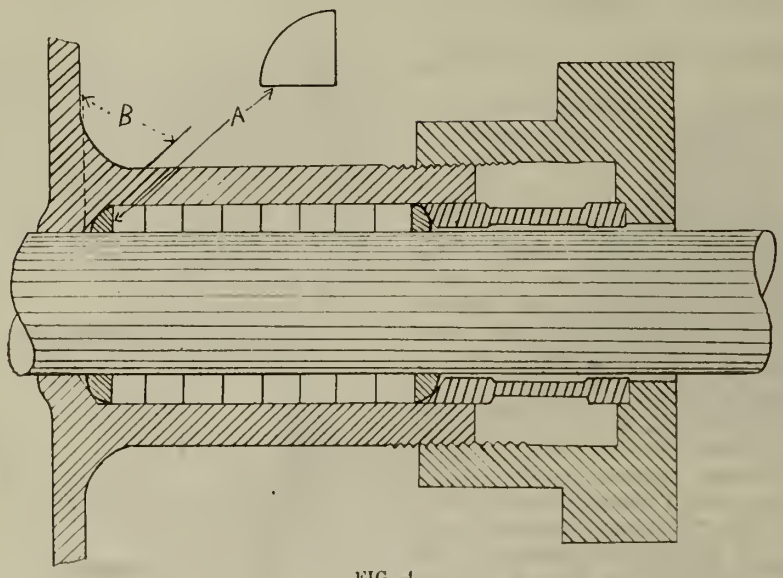

FIG. 4.

head in position, and if they are weak the head will rise and the machine will pound.

The discharge valve, of ample proportions to reduce the lift, is made of steel and is held in place by a cage which is easily removable for inspection. The steel seat for the discharge valve is forged into the safety head, multiple valves being provided in the larger sized units.

Note the unique method of jacketing. The entire lower part is insulated with cork, the upper part only being water jacketed. The suction valve is practically floated on its seat by a specially designed spring so that it opens to admit gas immediately at the beginning and remains open through the entire downward stroke. The suction pressure in the cylinder, therefore, is practically the same as that in the suction main; changing the tension of the valve springs should never be attempted without the use of an indicator as a hit or miss method will be sure to give poor results. For an illustration, refer to Fig. 2, which shows a simple valve for a six inch cylinder with a valve seat of 3-8 in. face, giving a bearing surface on top of the valve of 6 3-4 inches in diameter. Assuming a working pressure of 150 lbs., there will be a total pressure of 4977+lbs. on top and 4241+lbs. on the under side or an unbalanced pressure of 636+ lbs. This is taken care of by the spring action and it is readily seen how an incorrect spring tension can cause a considerable loss.

The oil inlet shown at the bottom of the figure connects an oil reservoir, not shown, with an oil well situated between the two sets of packing in the stuffing box. This permits the piston to travel back and forth through oil which effectually seals the packing and lubricates the rod as well.

There is no need of pumping oil into the cylinder of a machine of this type. The average ammonia compressor gets entirely too much oil. As it works in a closed system after it has been in operation for a short time, traces of oil circulate around the system, and as ammonia itself is slightly lubricating, this should be sufficient, especially when it is understood that some of the oil is carried into the cylinder by the piston rod.

The practice of shooting oil into the cylinder shoud be avoided as it is a clear waste of oil as well as a detriment to the system, as the excess oil is likely to form an insulating coating just where such a thing is not wanted. Only the very best grade of oil should be used in a compressor. In some systems, the temperature range is over 300 degrees F., and the oil must remain fluid under all conditions.

A good test is to draw off a sample of ammonia and into this place a small amount of oil in a tin can. If the oil remains fluid, it will be satisfactory so far as low temperature is concerned, as the temperature of the ammonia will be 28 degrees below zero.

To test for high temperature, heat a sample to about 300 degrees F. If it does not vaporize it is satisfactory for compressor work.

In all single acting machines, the stuffing box can easily be kept tight as it is subjected only to the low suction pressure, but in a machine such as is shown in Fig. 3, the stuffing box is one of the most important parts, and one where good design is absolutely essential if trouble is to be avoided. In this box, positive and uniform adjustment is obtained by dividing the packing into three parts, separated by two cages. A babbited ring is placed in the bottom of the box, closely adjusted to the piston and forming the bottom bearing for the packing. This may be replaced should it be necessary to turn down the rod.

The packing rings are next and then the first cage. The result is a chamber which is connected to the suction manifold by a pipe, through which any high pressure gas which passes the first set of packing is returned to the suction manifold. This leaves the second and third sets to work against evaporating pressure only.

The outer cage serves as an oil reservoir, oil being supplied by means of a pump. The outer packing rings are held in place by a gland, which is secured by three or more studs and nuts. All the bolts of the gland are connected by gears so that it is impossible to tighten one without tightening all.

In certain older type machines the stuffing box bottom was bevelled, as was the packing face of the gland, and considerable trouble was experienced in fitting square packing. This may be eliminated by using a ring such as is shown at A, Fig. 4. The angle, as shown at B, varies according to the designer but if a rounded ring is used, a square face is produced against which the packing may be tightened.

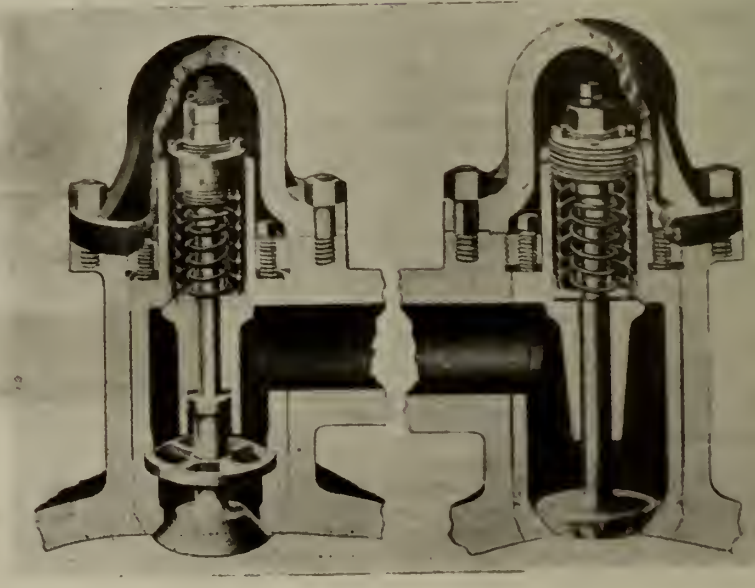

FIG. 5.

The fourth essential point mentioned in the beginning of this article, valve design and action, is of extreme importance as efficiency cannot be obtained if the valves leak or fail to work properly.

In designing a valve, it is necessary to know the amount of gas which must be passed through, and its velocity. It is customary to base the area of the suction valve on a velocity of 4000 feet per minute, and the discharge valve on 6000 feet.

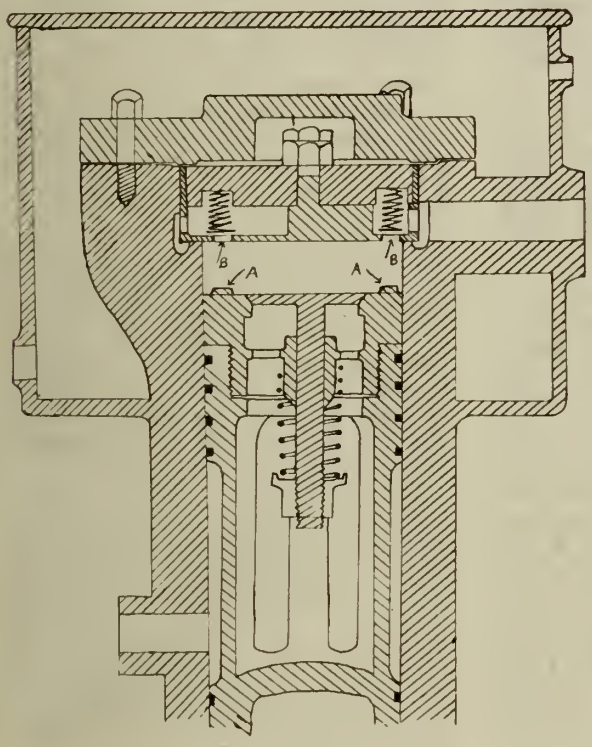

FIG. 6.

Table 1 gives the number of cubic feet of gas which must be pumped per minute at different suction and condenser pressures to produce one ton of refrigeration in 24 hours.

As an illustration, assume a ten ton compressor with back pressure of 13 lbs. and condenser pressure of 200 lbs. The table shows that 4.40.x10 cubic feet of gas must be pumped per minute. This amount may also be found by multiplying the area of valve opening by the velocity of the gas. It is therefore evident that the area can be found by dividing the amount by the velocity, in this case (4.4x 10) ÷ 4000–.011 square feet, or 1.584 square inches, corresponding to a diameter of 1.42 inches for the suction valve and 44÷6000–.00733 square feet, or 1.05552 square inches for the discharge valve. This corresponds to a diameter of 1.15 inches.

While valves proportioned in this way have been found satisfactory, it is usually advisable to have a lower velocity through the suction valve and very good results have been obtained with only 3000 feet per minute which calls for considerably larger valve opening than does 4000 feet.

Fig. 5 shows typical suction and discharge valves. The valve is ground to a seat in a cage which is inserted in the cylinder head. This in turn, is ground to a perfect seat, making an absolutely gas-tight joint. In some machines this joint is made by cutting a recess in the head and a corresponding shoulder in the cage and using a lead gasket. This makes a durable joint so long as the lead is not forced out, but as this often occurs, this type of joint is not reliable, and the ground joint as shown in Fig. 5 has come into general use. In the suction valve, shown at the left, the valve stem is smallest above the collar so that any break will occur above this collar, and there is no possibility of the valve falling into the cylinder. The collar works in a dash pot, which materially steadies its operation.

Ordinarily, the capacity of a refrigerating machine is stated in tons, one ton being the heat equivalent of 2,000 lbs. of ice at 32 degrees F., which has been melted into water at the same temperature or the amount of heat which must be abstracted from 2,000 lbs. of water at 32 degrees F. to freeze it into ice. The latent heat of ice being about 142 B. T. U., one ton of capacity is equal to 142x2000—284000 B. T. U. This is, however, misleading as no standard temperature at which this work shall be done has been adopted and a tonnage rate is merely nominal and actually misleading in some cases.

It is evident that the capacity of a compressor depends on the number of pounds of gas it will handle in a unit of time. The weight of gas depends on the efficiency of the compressor and the pressure at which it enters the compressor.

As the density of ammonia gas varies with the absolute pressure, a machine working under a suction pressure of 30 lbs. will have greater capacity than when working under 15 lbs. pressure. A low suction pressure is therefore essential, but the temperature at which the ammonia enters the coils must also be considered, as in calculating the net refrigerating effect of one pound of ammonia evaporated at a given back pressure, it is necessary to deduct from the latent heat of evaporation the energy used in coiling the ammonia itself. A good practical rule on this is that the ammonia should enter the coils at a temperature but little higher than that of the water flowing away from the condenser. It is usually considered advisable to reduce clearance as much as possible as any decrease in clearance increases efficiency. The economy of the compressor lies in its filling at the nearest possible point to the evaporating pressure and then compressing and discharging at the lowest possible pressure, as much of the contents of the cylinder as possible. If the piston does not travel to the end of the cylinder, the compressed gas remaining when the back stroke begins re-expands, and the gas from the suction line will not be taken into the compressor until the pressure in the cylinder falls below suction pressure. This may cause a serious loss not only of capacity, but also of power consumed in conforming gas not used. Many devices have been tried in order to reduce clearance—one of these being shown in Fig. 6.

There is a projecting ring A on the outer end of the piston. This fits into a groove B in which the valves are arranged. This practically eliminates clearance, but in modern, high speed machines it is not always advisable to do this, but to strive for a high efficiency of both, compressor and prime mover combined.

Cubic Feet of Gas to be Pumped per Ton

Temperature of Gas in Degrees F.	Corresponding Suction Pressure, Lbs. per Sq. In.	Temperature of the Gas in Degrees F.								
		65°	70°	75°	80°	85°	90°	95°	100°	105°

TABLE 1

A THREE HUNDRED TON AMMONIA COMPRESSER

THE accompanying illustration shows a refrigerating machine with Poppet valve steam engine, having a refrigerating capacity of three hundred tons, at Fall River, Mass. The compressors are of the horizontal water-jacketed safety type, with Poppet valve high-pressure steam cylinder and Corliss valve low-pressure steam cylinder. This plant is operated with a steam pressure of 175 pounds per square inch and the superhead of 150 deg., with steam consumption in actual performance being less than 10 pounds per 1 h.p. hour.

In some installations it is desired to operate plants only part of the time during 24 hours, and by introducing a brine storage tank of sufficient capacity it is possible to cool down a comparatively large amount of brine during the time the machine is operated, which may be circulated the balance of the time for maintaining the temperature as nearly as possible. The same results may be accomplished in another way by the direct expansion system.

With the direct expansion system special congealing tanks are used which are designed to keep the temperature from rising too high when the machine is shut down. These tanks are shallow pans, which are erected in any convenient location on the walls of rooms or refrigerator boxes. They are filled with light solution of brine, in which is submerged an ammonia coil. The brine is frozen during the time when the machine is operated and the melting of the frozen brine when the machine is shut down, absorbs the heat which leaks through the walls, floors and ceilings. It is of interest to note that there are two principal types of brine coolers in vogue at present, the shell and tube design, and the double-pipe style, and both of these methods are quite sufficient.

When comparatively small rooms or tanks must be refrigerated and the amount of surface in each coil is very small, the regulation of a direct expansion system becomes very difficult and the brine system should therefore be adopted. Such conditions are experienced in hotels, hospitals, dairies, ice cream plants and apartment houses. Here the question of proper regulation and control becomes paramount and the economy of the direct expansion system cannot be successfully utilized. The brine system is also made use of where a circulating medium is necessary in open tanks or vats for doing the refrigerating work.

The process of refrigeration is used in a large variety of applications other than those above mentioned, of which the principal are breweries, cold storage plants, abattoirs and packing houses, department stores and chocolate factories, fur storage, drinking water cooling systems, beer storage depots, fruit pre-cooling plant and steel tempering systems.

As shown in the photograph the heart of every refrigerating equipment is the ammonia compressor, the successful performance of which is absolutely necessary to obtain the desired results. It is therefore of great importance to select the most dependable and economical design of compressor which the market affords. The horizontal safety compressor offers the unusual combination of safety in operation and the highest degree of economy. The valves are located in the bottom and not in the heads, which eliminates any possibility of an accident.

Another question which should be given consideration at the same time as the ammonia compressor is the kind of motive power which will best suit the local conditions. The cheapest method of operation will naturally be the most attractive. Current from hydro-electric stations may be obtained in a few localities at less than ½c a kilowatt hour. Electricity will be hard to compete with by any other forms of power in such places. Close proximity with coal mining districts will offer this fuel at low prices and steam power will prove advantageous. The cost of fuel or crude oil in about two-thirds of the United States and the great success of high-grade oil engines are reasons why this power has been adopted in so many recent installations.

There are hundreds of plants in operation with all types of motive power, including simple tandem and cross-composed Corliss steam engines, Poppet valve engines, using superheated steam, oil engines, water turbines and electric motors. Crude oil engines have also been utilized in all sizes of plants up to 800 tons refrigerating capacity, and are acknowledged as a form of power of the same dependability as first class steam engines.

The compression side of a refrigerating plant constitutes the machine, engine room connections, with oil and scale separators, liquid receiver and the ammonia condenser. The work of refrigeration is merely the extraction of heat, which must be absorbed and carried away. To absorb it refrigerating surfaces are required of a design and proportion to suit the conditions and work to be accomplished. The most common form is pipe arranged in coils in the rooms, refrigerator boxes, tanks and coolers. There are two methods which are in extensive use known as the direct expansion system and the brine system.

The direct expansion system is the most economical method and is used in the majority of plants. Ammonia circulating pipes are installed directly in the rooms or tanks where the work is to be done, and the ammonia is expanded directly into these pipes. The question of leaks is never considered a factor owing to the perfection in the construction of such piping systems.

The brine system is an indirect method of refrigeration which was in use before the direct expansion system was first introduced. Instead of directly expanding ammonia in pipes in the rooms, the ammonia is utilized in submerged coils, shell coolers and double-pipe coolers for cooling brine, and this brine is a circulating medium which is conveyed through the refrigerator pipes in the rooms or tanks for carrying off the heat.

The double-pipe coolers are usually made of 2 in. and 3 in. pipe, with the brine passing through the inner pipe and the ammonia expanded in the annular recess between 2 in. and 3 in. pipes. These are usually twelve pipes high, 20 feet long, and in every case they are proportioned to the quantity of brine which must be handled and the range that is necessary to do the best work. Brine coolers of the overflow or submerged type are also used in some

300-TON REFRIGERATING MACHINE.

instances, but the two styles above mentioned are adopted in almost every instance.

There are quite a few plants which have adopted the indirect method of air cooling for refrigerated rooms or boxes. By this system air is circulated over the ammonia coils in a bunker room and introduced into the cold rooms through ducts. Sometimes the air coolers are arranged with brine flowing over them. There is also a brine spray system which cools the air by passing it through the spray. All of these systems fall under the heading of "indirect methods." There are two advantages to indirect refrigeration. The first is the rapidity with which products may be reduced in temperature on account of the forced draft, and the other is the absence of coils in the rooms, eliminating the presence of frost or moisture and assuring the greatest cleanliness.

While at first glance these two advantages are very important, the indirect method has never been universally adopted, because in the the average case the disadvantages more than offset any advantages. The very bad feature is the fact that the rapid circulation of air increases the shrinkage of goods to a large degree. It has been found that the shrinkage of meat would be as much as 100 per cent. more in 48 hours when the indirect method is used as compared with the direct system. Apples, eggs, and other similar products which lie in cold storage for several months, not only suffer greatly from this excessive shrinkage, but also lose a good part of their flavor. The danger of introducing air which has passed over odoriferous products in other rooms is considerably increased. Not long ago, 50,000 eggs were destroyed through such an occurence.

It may be of interest to consider some of the advantages of the direct method. By properly distributing pipe coils in cold storage rooms, it is possible to insure a certain natural circulation of the air, which will reach products stored in the room at every point. This natural circulation causes no undue shrinkage, maintains a perfectly even temperature, and on the whole is more simple to handle than an indirect plant. Of course in installations such as fur storage rooms there is no loss through shrinkage, and the indirect system may prove more satisfactory on account of the absence of coils in the rooms and the elimination of any possibility of dripping.

It is obvious that in large plants, or even in equipments of moderate size, it is advisable to install two refrigerating units, as part of the time one of the units can be shut down and furthermore, in case of an accident to one unit the other could take care of the plant until repairs are made.

GOVERNOR FAILED AND CAUSED FATALITY

VANCOUVER.—Evidence given by W. H. Padden, chief engineer at the Robertson-Hackett mill, where James Bogle lost his life recently through the bursting of a fly-wheel, showed that failure of the automatic governor regulating the speed of the engine, was responsible for the catastrophe.

The witness stated that he discovered the driving belt of the governor on the floor of the engine-house, but did not attach any importance to this, as he expected the governor to act and automatically shut off the steam. Instead the engine commenced to "race," and Bogle, who was his assistant, ran to the valve near the wheel in order to stop it. By this time, however, the speed had increased to such an extent that the tensile strength of the wheel rim was insufficient to stand the strain, and it went to pieces, the unfortunate man being struck and instantly killed by the flying fragments.

Witness managed to make his way through the escaping steam to the top of the boilers, where he shut off the main valves.

Portions of the wrecked wheel flew a distance of forty feet, crashing through the room occupied by the saw-filer, who narrowly escaped injury.

Padden, who was the only witness of the accident, was unable to explain the cause of the failure of the governor, but said that about ten years ago a piece of valve rim became imbedded between the ports of the governor and prevented it working, the engine speeding up in that instance, but being fortunately checked without disaster. He believed that in the present instance something must have become dislocated inside the governor and caused an obstruction which prevented it from closing.

Witness explained that periodically he examined and tested the governor by taking off the belt and satisfying himself as to its working condition. He had done this about three months ago.

The jury returned a verdict to the effect that James Bogle died as the result of being accidentally struck by portions of the wrecked wheel.

The Paragon Electric Co., Old Colony Building, Chicago, has issued a pamphlet entitled, "Grounding Facts." This publication is descriptive of the grounds manufactured by this firm in the cone and cylinder shapes. In addition to the material of this nature given in the pamphlet much valuable data are included on the subject of grounding electric circuits in general.

Don't try to economize on packing by attempting to run it after it has been burned or become hard enough to lose its resilience. Packing is a small item compared to turning up the rod. Besides it is a lot more trouble and you can generally find more profitable use for your time than to stick around nursing a stuffing box full of worn-out packing.

They All Think So

Letters From Everywhere, Supporting the Semi-Monthly Issuing of POWER HOUSE. Read Them

"I certainly do favor the change to a semi-monthly, and I think we should all appreciate it by handing our old friend POWER HOUSE to our engineering friends who are not subscribers. I think a subscription charge of $2.00 a year would not be out of the way."—Mr. James Dixon, Woodstock.

* * *

"Re changing POWER HOUSE to a semi-monthly magazine. I believe it would be a great benefit to subscribers. As a monthly paper it has been a great help in many ways. As to changing the present price I do not know where a subscriber could get the same information as has been published in POWER HOUSE. I cannot see why any subscriber should have any reason to object if the price is raised. If a subscriber has to pay twice or even three times as much as the present subscription price I consider he would be getting his information very cheap."—Mr. Thos. Lemon, Waterworks Dept., Haileybury.

* * *

"You ask what I think of POWER HOUSE twice a month, I for one would think it would be a benefit to all. I have always said it was a great drawback having it come only once a month. I have taken POWER HOUSE since the first copy was printed. I always look for it. **POWER HOUSE is a great help to the beginner,** and it will make some of the old fellows stand back and take notice."—Mr. H. Kendrick, Studebaker Corp., Walkerville, Ont.

* * *

"Re the publication of POWER HOUSE twice a month, I for one would be very pleased to get it that often. As regards the subscription price, if we get two copies a month instead of one, I should judge two dollars a year would not be out of the way."—Mr. J. Collier, Medicine Hat, Alberta.

* * *

"I would be delighted to have POWER HOUSE twice a month, as I think it is one of the best magazines printed.—Mr. J. A. Cooper, Montreal, West.

* * *

POWER HOUSE *stands for the upbuilding of efficiency in power plant equipment and service; that's the reason* POWER HOUSE *is supported by the best engineers.*

If you are not now a subscriber to POWER HOUSE, *send in your one dollar today and secure a twice-a-month publication brim-full of real live-wire editorial and advertising information.*

You know.

The Proper Lubrication of Air Compressors

The Lubrication of the Air Compressor Has Been a Subject of Frequent Debate, and For This Reason the Following Article, Published Through the Courtesy of the Compressed Air Society, is of More Than Usual Interest

By H. V. CONRAD

SATISFACTORY lubrication of air compressor cylinders is attained by securing (1) the reduction of friction to a minimum and (2) elimination of carbonization of the oil as far as possible.

For the proper reduction of friction, oil chosen should have sufficient body to sustain the weight of the moving parts and to form a seal between the piston rings and the cylinder walls, and still not absorb excessive power in the overcoming of the viscosity of the oil itself.

The objections to air cylinder oils which allow more than the very slight amount of carbonization which appears unavoidable, are, of course, well known, but may be briefly stated for the purpose of clarifying what follows:

Carbonization of the oil allows the accumulation of deposits of carbon which are sticky in the early stages of their formation but hard and flinty later. Such deposits accumulate on the cylinder pipes and eventually in the air receiver.

Sticking or partial closing of the valves and their consequent failure to act properly is probably the chief objection to this action from the standpoint of the efficient operation of the compressor.

The formation of excessive carbon deposits is apt to be due to any one or more of the following causes:

1. The ill-advised use of some oil, such as a steam cylinder oil, which easily decomposes in the heat of the air cylinder.

2. The use of oils of too great a viscosity—commonly referred to as "too heavy oils." These do not atomize readily and, therefore, remain too long upon the hot cylinder walls, etc., thus baking down to sticky carbon deposits.

3. The use of too great quantities of oil, which has the same effect as the use of too heavy an oil, as far as the carbonization is concerned.

4. The failure to provide a proper screen over the air intake of the compressor, thus allowing free entrance of dangerous dust (especially coal dust).

The objections to this carbonization aside from the sticking of air valves and choking of the air passages is the menace of fire entailed by carbon deposits. Carbon particles torn loose from them may become incandescent from causes which could not be anticipated by the compressor manufacturer. If such incandescent carbon particles should happen to come in contact with "oil vapor" given off by the lubricating oil, a fire might possibly be started whose menace would be small or large depending upon how much carbon had been allowed to accumulate in the compressor and piping to the receiver. If these are kept properly cleansed at all times there should never be a time of any danger.

This oil vapor is given off from a lubricating oil at a certain temperature called its "flash point" just as steam rises from water at a certain point.

Heat of Air Compression

The selection of an air cylinder lubricant is, of course, governed to a considerable extent by a knowledge of cylinder temperature it must withstand. Knowing the air pressures, the corresponding temperatures are ascertained fairly accurately, as shown in Table No. 1.

This table gives the final temperature in the cylinder at the end of the compression stroke, for single stage, also for two stage (or compound) compression, when the free air entering the cylinder is 60 degrees F.

Table No. 1—Cylinder Temperature at End of Piston Strokes

Air Comp. to	Final Temp. Single Stage	Final Temp. Two Stage
10 lbs. gauge	145 deg. F.	
20 lbs. gauge	207 deg. F.	
30 lbs. gauge	255 deg. F.	
40 lbs. gauge	302 deg. F.	
50 lbs. gauge	339 deg. F.	188 deg. F.
60 lbs. gauge	375 deg. F.	203 deg. F.
70 lbs. gauge	405 deg. F.	214 deg. F.
80 lbs. gauge	432 deg. F.	224 deg. F.
90 lbs. gauge	459 deg. F.	234 deg. F.
100 lbs. gauge	485 deg. F.	243 deg. F.
110 lbs. gauge	507 deg. F.	250 deg. F.
120 lbs. gauge	529 deg. F.	257 deg. F.
130 lbs. gauge	550 deg. F.	265 deg. F.
140 lbs. gauge	570 deg. F.	272 deg. F.
150 lbs. gauge	589 deg. F.	279 deg. F.
200 lbs. gauge	672 deg. F.	309 deg. F.
250 lbs. gauge	749 deg. F.	331 deg. F.

Variations from these temperatures will occur in actual practice due to water jacketed air cylinders and radiation, tending to lower the temperature at the higher pressure. But at, say, 50 pounds pressure and lower, the heat is likely to be somewhat greater than given by the table, particularly if the compressor is run at high speed and also if it is not water jacketed.

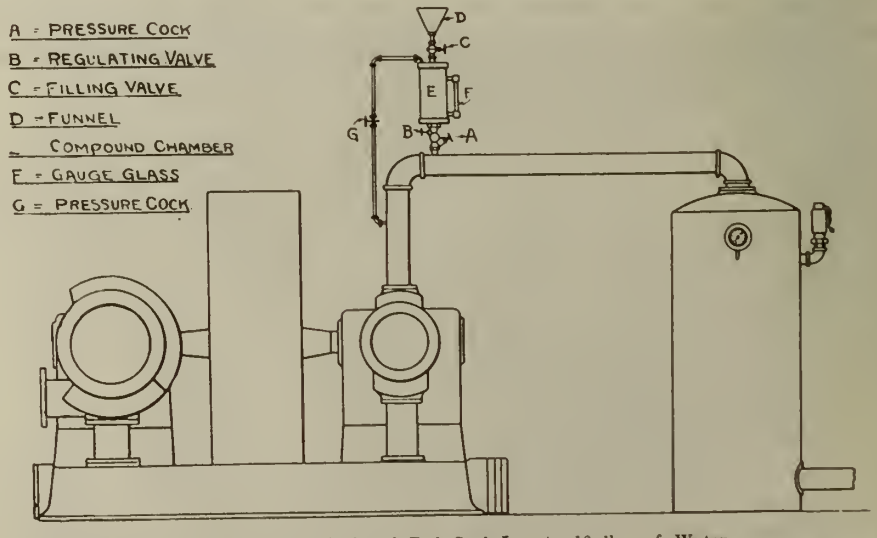
Relation of Oil Flash Point to Cylinder Temperature

The natural inference of the reader after noting the temperatures in Table 1, is that he must select an air cylinder oil whose flash point is higher than the maximum temperature apt to be encountered within the air cylinder. As a matter of fact, this is not the case and it need only be carefully noted that the study of the air cylinder temperatures is useful mainly in testing lubricating oils to determine their resistance against breaking down into carbon, etc. But such temperatures cannot be taken as limits establishing the highest allowable flash point for a lubricant safe to use in the air cylinders.

Qualities of Cylinder Lubricating Oils

For average normal conditions, the oil should be a medium bodied pure mineral oil of the highest quality, not compounded with fixed oils such as animal or vegetable, and should be carefully filtered in the final process of manufacture.

Quite a range of oil composition is permissible for lubricants approved for



COMPOUND—Mix 1 lb. of Red Seal Lye to 18 lbs. of Water.

To use Compound: Close Cock "A" and "G," open Valve "C" and fill Compound through funnel "D," when chamber "E" is filled close Valve "C," open Cock "G" and "A" and regulate feed by Valve "B"; use about 70 drops per minute.

DEVICE FOR CLEANING CARBON IN AIR DISCHARGE LINE AND RECEIVER OF AIR COMPRESSORS

this work, which are manufactured under the above conditions. Primarily a distinction must be made between those oils having a paraffin base, as distinguished from those having an asphaltic base.

From a strictly operating standpoint —so it is claimed by some lubricant manufacturers—there is no distinction between these two classes of lubricants as to their desirability as compressor cylinder oils, provided that both have been properly filtered in the process of manufacture to remove the carbon forming elements. If any carbon should be formed, however, such carbon deposited by the asphaltic base oils is of a light, fluffy nature and easily cleaned out, whereas that deposited by the paraffin base oil is very adhesive and characterized by the hard, flinty nature.

Paraffin Base Lubricating Oils

Merely as a guide to aid the operator in specifying the qualities to be possessed by an air cylinder lubricant recommended for average duty, the following table is presented:

Table No. 2—Physical Tests of Paraffin Base Oils

	Minimum	Average	Maximum
Gravity, Baume	28 to 32 deg.	25 to 30 deg.	25 to 27 deg.
Flash Point, Open Cup	375 to 400 deg. F.	400 to 425 deg. F.	425 to 500 deg. F.
Fire	425 to 450 deg. F.	450 to 475 deg. F.	475 to 575 deg. F.
Viscosity (Saybolt) at 100 deg. F.	120 to 180 sec.	230 to 315 sec.	to 1500 sec.
Color	Yellowish	Reddish	Dark Red to Green
Congealing Point (pour test deg. F.)	20 to 25 deg. F	30 deg. F.	35 to 45 deg. F.

It is suggested that these oils within the range expressed by the minimum figures be used for light duty of low-pressure and temperatures, while those expressed by maximum figures should be used for high pressures and temperatures.

It is recommended that any paraffin base lubricant intended for use in "all standard air compressors," should meet the physical tests imposed by the average range of figures given in the middle column of the above table. The above wording "standard air compressors" is to be interpreted as including the following types of machines:

(a) Low pressure up to 100 lb. compressors, which may be either small sized single stage units, or larger sized compound machines.

(b) High pressure compressors which are constructed with the proper number of stages, so that no excessive temperatures are ever reached.

In other words, this lubricant of average test figures is always recommended unless a compressor manufacturer specifies in his literature that a high flash point of oil should be used to meet the conditions peculiar to his machine. It is thus obvious that it is never necessary that a lubricant should possess a flash point as high as 500 degrees unless abnormal conditions of high temperature prevail. Such high flash point oils have an unusual tendency to produce carbon deposits.

Asphaltic Base Lubricating Oils

This group of oils is considered separately for the reason that the lower limit of gravity stated in the above table, viz., 25 degrees baume, eliminates the entire group from consideration—which is not the intention of this article.

As a guide for the selection of a suitable oil, the following table is given:

Table No. 3—Physical Tests of Asphaltic Base Oils

	Minimum	Average	Maximum
Gravity, Baume	20-22 deg. F.	19.8- 21 deg. F.	19.5-20.5 deg. F.
Flash Point, Open Cup	305-325 deg. F.	315-335 deg. F.	330- 375 deg. F.
Fire	360-380 deg. F.	370-400 deg. F.	385- 440 deg. F.
Viscosity (Saybolt) at 100 deg. F.	175-225 sec.	275-325 sec.	475- 750 sec.
Color	Pale Yellow	Pale Yellow	Pale Yellow
Congealing Point (pour test)	0 deg. F.	—0 deg.F.	—0 deg. F.

For general all around use, it is conceded that the recommendations given in Tables No. 2 and 3 above cover the situation as well as possible, special cases, of course, requiring investigation and special consideration before making recommendations.

Proper Quantity of Lubricating Oils

The quantity of lubricating oil to feed to the air cylinders of the compressors, cannot be stated in exact terms due to the varying viscosity of different oils, the heat of compression and the size of the cylinder. It may be stated in general, however, that after the cylinders have acquired smooth and polished surfaces, the quantity should be reduced to the lowest limit to avoid the possibility of the accumulation of carbon and sooty deposits within the system due to excessive use.

The following basis of quantity given in Table No. 4 is recommended, subject to above modifications for these cylinders or equivalent sizes, operating under normal conditions.

Table No. 4—Quantity of Air Cylinder Lubricant Required per 10 Hour Day.

Diam. of Cylinder Inches	Size of Cylinder Inches	Displacement per Minute Cubic Feet	Piston Speed Feet per Minute	Sq. Ft. of Cylinder Wall Swept by Piston	Drops of Oil per Minute	Drops of Oil per 10 Hours	Sq. Ft. Oiled per Drop	Number Pints Oil Required per 10 Hours.
8	8x 8	120	344	718	1	600	718	.0375
12	12x12	320	408	1230	2	1200	613	.0750
18	18x18	880	496	2340	4	2400	585	.1500
24	24x24	1730	550	3450	6	3600	575	.2250
30	30x30	2940	600	4700	8	4800	590	.3000
36	36x36	4550	644	6070	10	6000	607	.3750
42	42x42	6700	696	7600	12	7200	633	.4500

*Figures of last column are based upon an estimated 16,000 drops per pint of oil at 75 degrees Fahr.

It will, of course, be carefully noted and clearly understood that the results in the last column of Table No. 4 are based upon the assumption that under average conditions of temperature and usual range of oil viscosities, a pint of oil will contain an average of about 16,000 drops. It is understood of course that these figures are offered merely as an approximate guide and that every individual must exercise his own judgment in modifying them wherever his own particular set of working conditions is unusual.

A leading authority on compressor engineering contributes the following:

"The best way to determine the proper amount of lubrication is to take out the valves from time to time and examine the cylinder. All parts should feel that there is oil thereon. If they feel dry the lubricators should be adjusted to feed a little more oil, whereas if oil lies in the cylinder and its parts show excessive oil thereon, the quantity fed by the lubricators should be reduced. By thus examining the machine a few times, the proper amount of oil can be determined to suit the characteristics of the particular lubricant used and the conditions under which the machine operates." This is a better way to finally determine the quantity of oil required than by adopting without this experimenting any tabulated number of drops.

Periodical Cleansing of System

The best of lubricating oils will cause the deposit of enough carbon in the compressor system to necessitate the periodical cleansing of it.

For the removal of carbon, the machine operator should confine his efforts to the use of soap suds. A good cleansing solution is made of one part of soap to fifteen parts water. These suds should take the place of oil for a few hours, and be fed into the air cylinders about once a week, either by means of a hand pump, or through the regular lubricator at a rate about ten times as rapidly as that of the oil. The cleanliness of the air valves when inspected, as they should be periodically, will indicate whether greater or lesser applications of the soap suds should be made. After using soap suds, open the drain cock of the air receiver, and of the inter-cooler in the case of compound machines, to draw off any accumulated liquid. Oil should be again used for half an hour before shutting down the machine in order to prevent rusting the cylinder and its fittings. Never use kerosene,

gasoline or lighter oils in an air cylinder for any purpose whatever, because of their volatile nature under heated conditions.

Cleaning Air Receiver and Piping

It often happens that oil, carbon and other foreign matters are deposited in the air discharge lines and the air receiver. A practical method of cleaning these is shown in cut attached, where a receptacle made of 6-inch pipe is shown set on top of discharge pipe. The cut shows plainly the construction and what the different parts represent. If a mixture of one pound of Red Seal Lye and eighteen pounds of water is passed into the discharge line at the rate of 60 or 70 drops per minute, while the compressor is running, this will eat out all the accumulation on the surface of the pipe and in the receiver, and if the blow-off valve of the receiver is open, all of this foreign matter will be discharged therefrom. This cleaning solution can be used every month or two or depending on how much accumulation may be in the receiver.

The proper quantity of oil to be fed to steam cylinders is much greater than to air cylinders due to the constant washing away of the oil by the steam. Approximately four times as much oil will be needed in the steam cylinders as in those for air, subject, of course, to variable local conditions.

Depending on its viscosity, a pint of steam cylinder oil will furnish from 5,000 to 8,000 drops, and taking an average of about 6,500 drops, and four times as much oil as air cylinders of same size and working at same piston speeds, as given in Table No. 3, the recommended amounts to feed the steam cylinders or their equivalents are given in the following.

Table No. 5—Quantity of Oil for Steam Cylinder Lubrication.

No. Drops per Min.	Size of Cylinder Inches	No. Pints Oil Required per 10 Hours
4	8 x 8	.4
8	12 x 12	.75
16	18 x 18	1.5
24	24 x 24	2.25
32	30 x 30	3.0
40	36 x 36	3.75
48	42 x 42	4.5

These figures are approximate only, and will vary with the steam conditions, the kind of oil used, and its method of introduction into the steam, also with the boiler compound carried by the steam into the cylinder.

Observations on Changing Tested Oils

When the operator of an air compressor succeeds in obtaining lubricating oils that are giving satisfactory results, he should be very cautious about making a change to other grades, particularly if cheapening the cost is advocated by purchasing and sales agents. But if a change is decided on, the performance of the new lubricants should be most carefully checked up before damage can occur to the rubbing surfaces of the compressor, and to see that no increased amount of deposit collects on the inside walls of the air receiver.

The most satisfactory way to get the quickest results is to put up the problem of lubrications to the local experts of any reputable lubricating companies, and to be governed by their recommendations, which, however, should be based on the foregoing statement.

Is the Heating of Feedwater by Steam Economical?

Live-Steam Heating Used For Many Years in Marine Practice With Good Results—Discussion of Advantages to be Derived and Circumstances Under Which Live Steam Heating is Advisable

By E. STANDIFORD

FEW questions connected with the steam boiler have been more hotly contested than the heating of feed water by means of live steam. On the one side theorists have argued from thermo-dynamic laws the impossibility of securing economy by the heating of feed by the condensation of steam drawn from the boiler; on the other side practical men point to the many installations of live-steam heaters in which economy is secured.

A large body of marine-engine builders and shipowners have for many years used some system of live steam-heating with results which were and are apparently satisfactory. At the same time it does not admit of question that there is nothing to be gained directly by live-steam heating, and in order to reconcile the obvious contradiction we must assume that something not yet understood goes on inside the boiler.

A careful experiment was made upon an experimental boiler of a locomotive type; the shell being 3 feet 6 inches in diameter, and contained 47 3-inch tubes, 6 feet 10 inches long. The firebox was 3 feet 5½ inches by 3 feet 3 inches by 4 feet 8 inches deep; the grate area was 7.5 square feet and the heating surface 315 feet.

The feed water was supplied by a pump worked from the cross head of the main engine. When supplied cold it entered the boiler through an opening in the side; when the live steam feed heater was in use the cold feed entered at the top of the boiler and passed through the heater before finally escaping into the water space of the boiler. The heater was constructed especially for the tests; it consisted of three shallow tin-plate dishes superposed and connected to each other by distance pieces; the feed water admitted by the feed pipe to the bottom of the upper dish overflowed into the second. A central overflow pipe maintained a constant depth of about ⅝ inch in this dish and overflow took place through this pipe into the bottom dish, from which it overflowed and dropped into the water space of the boiler.

The heater was supported in the steam space by longitudinal stays. It was made as large as could be conveniently got into the very constricted space available, but could with advantage be made larger, the feed water not remaining in contact with the steam for a sufficiently long interval of time to enable it to attain full boiler temperature before mixing with the water in circulation.

The temperature immediately before overflow was measured by means of a mercury thermometer placed in a pocket through the boiler crown which rested on the bottom of the lowest and largest tray. The steam produced was used for driving a brake-load experimental engine whose load could be maintained constant or varied as required. The whole plant was especially equipped for testing, and all the measurements of coal and water consumption, temperatures of water, steam and flue gases, etc., were made with great accuracy. Four tests were carried out, the first two having the heater in operation but with very different loads on the boiler, the other two without the heater, but with rates of evaporation similar to those in the first pair.

In all the tests the temperature of the water entering the boiler was 40 degrees Fahr., and the temperature of the steam 339.6 degrees Fahr. In the light-load trials the feed water left the heater at a temperature of 313.8 degrees Fahr., a gain of 273.8 degrees; in the heavy-load trials the gain was 255 degrees. Probably a conservative estimate would place the increased efficiency due to the use of the heater under exactly identical conditions of working as 5 per cent. in the light power trial, and 8 per cent. in the heavy power trial, and had the heater been sufficiently large to enable the feed water to be heated up to full boiler temperature, these gains could have been increased to at least 6 and 9 per cent. respectively.

With a view to throwing some light on the reason why such a method of feed heating should lead to more economical working, a series of experiments were afterwards carried out on an open cast iron vessel about 8 inches in diameter

and containing about three inches of water; this was heated up by means of a ring of gas jets giving a flame whose mean temperature was 2,000 degrees. The temperature of the water side of the plate was measured by means of a platinum-iridium thermo-couple placed in intimate contact with the plate, a shallow depression being made in the plate to receive the point of the couple.

The temperature of the water was taken by means of a mercury thermometer. It was found that the difference in temperature between the plate and the water gradually diminished from 70 degrees to 0.5 degrees. In these experiments the water was stirred vigorously during the whole period of heating, and it confirmed what has been brought out by other experimenters that, under given conditions of heat transmission the difference between the temperature of the water and of the water side of such a plate is very much greater when the water is being heated up to boiling point than when it is in ebullition, and this although the water is circulating vigorously over the hot surface.

In these experiments, too, however great the ebullition, it was found impossible to increase the temperature of the water side of the plate to more than 213 degrees Fahr., and in the great majority of cases the temperature was, as nearly as could be measured, identical with that of the water. As a result of these experiments I found it would appear reasonable to assume that over the tubes, in the neighborhood of the feed inlet to a boiler, the temperature of the water side of a plate, and, therefore of the fire side of the plate for a given rate of heat transmission was appreciably lower; as much as 40 degrees Fahr. lower and at least 20 degrees Fahr. lower with the heater in operation than without it. At first sight it would appear that such a small difference is totally inadequate to account for any appreciable difference in heat transmission and hence in the efficiency, for since the temperature of the gases has a mean value of about 1,200 degrees Fahr., the mean difference between the temperature of the gases and that of the tube surface will be about 850 degrees Fahr., and a difference of 20 degrees Fahr. in this, assuming heat transmission to vary as difference of temperature, would only affect heat transmission by a little over 2 per cent. Assuming the heat transmission from gas to plate to vary as the square of the temperature difference, this increases the effect, say roughly 5 per cent.

Investigations on the transmission of heat to the water jacket of an internal-combustion engine, however, appear to indicate that, as in this case, so in the case of a steam boiler, a much greater proportion of the heat is transmitted by direct radiation than has hitherto been assumed; hot gases even when in a non-luminous state having been shown to possess the property of radiating heat in a marked degree, up to about 40 per cent. of the total heat interchange apparently taking place by radiation.

Experiments also indicate that the transmission of radiant heat at such temperatures that occur in the hot gases is proportional to the difference of temperature raised to the Nth power where N apparently has a value approximating to 3.5. Adopting this value, a drop of 20 degrees Fahr. in the tube temperature would give an increased transmission by radiation of practically 9 per cent.

Even though the great proportion of heat is transmitted by conduction from gas to metal it appears however that a cooling of the metal surface is likely to be more effective than a corresponding increase in the temperature of the hot gases. As is well known, transmission of heat by conduction from stratum to stratum of a hot gas is a mass phenomenon, and depends on the velocity (therefore greatest near the centre of a tube where velocities are greatest) on the difference of temperature and increases directly as to density.

Owing to the rapidity of the motion heat is readily transmitted from the central filaments in such a tube to those nearer the walls, but with considerably

BELT LACER.

less ease in the immediate neighborhood of the walls where the motion is comparative by sluggish. In the neighborhood of the walls however the gas is cooled down to a temperature approximating much more nearly to that of the cool surface, its density is considerably greater than in the center of the tube and is greater as the tube surface is cooler, so that any cooling of this surface has a double effect in increasing the rate of transmission.

On the whole it would appear that these differences in the rates of heat transmission, though severally small, when acting cumulatively offer a possible explanation of the gain in efficiency undoubtedly obtained in series of tests by the use of the live-steam feed heater. The reason for the greater gains in efficiency in the case of the more heavily worked boiler is probably due to a greater portion of the heating surface being occupied in heating up feed water rather than in the process of evaporation in such a boiler than in one more lightly worked. With feed water at 40 degrees Fahr. over 25 per cent. of its total heat is given to the water during this process of heating up, and the proportion of the whole heating surface affected by this must be roughly proportional to the weight of cold feed per minute. From this and other considerations it may be expected that such a heater will be found to be most effective; (1) In a given boiler when this is most heavily worked; (2) when no economiser is fitted to take advantage of the heat rejected in the flue gases; (3) where the boiler is fed with cold water; and (4) other things being equal, in a boiler in which the heating surfaces are somewhat incrusted.

A NOVEL BELT LACER

By Frank C. Perkins

The accompanying illustration shows a unique and effective belt lacer in operation. It is stated that this machine laces any width or thickness, and laces a 6 inch belt in three minutes. It saves man-time, machine-time and money, and makes a durable, flexible lacing.

The photograph shows the toggle construction of the new lacer and why it is possible to develop over 50 per cent. more power for pressing hooks in flush with the surface of a belt than with older types of devices. It is made of crucible steel, malleable iron, and tool steel, and all of the working parts interchangeable.

The clipper hooks are carded, long and short ends alternating. This card is easily removed after the hooks have been locked into the tool. The cards contain 37 hooks, each enough for a 6-inch belt, and with rawhide pins, one for each laced joint. In lacing belts narrower than 6 inches, it is only necessary to cut each edge of card with scissors furnished, bend slightly back and cut through centre. This can be done without displacing any hooks.

This lacing is flush with the belt on both sides. No holes are punched, nothing taken out to weaken it and no fibre is cut to allow belt to ravel. The hooks are zig-zag so that the pull is distributed over a large area of belt. The hooks are made from a special steel wire of an analysis that combines great tensile strength with rigidity and wearing qualities. Actual tests have proven that each hook will stand a pulling strain of 60 pounds, equal to over 400 pounds per inch of belt.

There is no ladder needed; as one of the greatest advantages of lacing belts with this device is the fact that the work is done right beside the broken or stretched belt, without removing the belt from the shaft. The lacer is set on the floor or a box, and a row of hooks of the proper width is then placed in the tool. The squared end of belt to be laced is then inserted, and, by depressing the levers the hooks are deeply embedded into the end of the belt, flush with both surfaces, leaving a uniform row of loops extending across the belt end. When the other end is similarly treated the two ends are brought together round the face of the lower pulley in such a way as to intermesh the loops. A rawhide or fibre pin is slipped through these loops and the job is finished.

The Making of Artificial Ice from Raw Water

Pure Ice is Made by the Raw Water Ice Plant at an Economical Figure—The Article Describes Some Steps in the Process of Raw Water Ice Making

By JAMES W. PATTON

NOT so many years ago the common idea was that "ice was ice"; whether cloudy or clear, pure or contaminated was never considered by the consumer. The product of the neighboring pond was readily sold, regardless of the fact that before freezing it was the dumping ground of the entire vicinity. However, agitation, due to increased knowledge on the part of the consumer and health officials, increased competition and other causes forced a change, and in order to be saleable the ice company's product had to be clear and transparent in appearance as well as chemically pure. The distilled water plant was the first result of this change in public opinion, and for many years engineers considered that it was necessary to install and to use a very expensive system in order to make a saleable product. The distilled water system was the only recognized standard type and continued in almost universal use until a few years ago, when a demand for a cheaper product forced another change. In order to obtain the distilled water a certain quantity of steam is necessary, and this of course led to the use of the steam engine as the standard form of power, as this could be used in the production of the distilled water; as it was found that the amount of exhaust from a simple Corliss engine driving an ice plant was just about sufficient for the purpose. It is evident that under these conditions of manufacture the more efficient type of power plant could not be considered as oil engines, gas engines, or electricity would not furnish the required amount of steam.

When the demand for a cheap ice, which was also pure, became general, a radical change was made, and the raw water ice plant was the result. This system makes it possible to manufacture ice from ordinary water without the expense and care incidental to the operation of the older type plant. Fig. 1 shows a standard type gravity distilling apparatus in which the water, after being condensed in the steam condenser passes through the reboiler, flat cooler, filters and storage tank into the cans, gravity being the motive power. It is plainly evident that at the best this is a complicated system, expensive to install and requiring skilled attendants. In plants where all the ice is made from distilled water, only about 80 per cent. of the steam produced by the boilers can be saved for filling the cans, therefore it is necessary to equip the plant with engines which will produce the necessary power with less steam than is needed for filling the cans, otherwise fuel economy will not be obtained. This makes it necessary to install an evaporating plant, and the economy of the entire plant is an average of the economies of the steam-producing apparatus, the evaporating machinery and the boiler plant. Raw water ice making is the natural companion of economical motive power as all modern developments have been toward reducing the cost of a ton of ice, and unless the entire plant is economical in its operation it is useless to install a cheap motive power. Obviously the elimination of one series of operations is a step in the right direction, and the ideal plant of to-day is the one which uses raw water frozen in the removable type of cans. Water, in freezing, will throw off impurities which can be removed in no other way except by boiling and condensing. An illustration of this is in the well-known Plate system, where the impurities are retained in

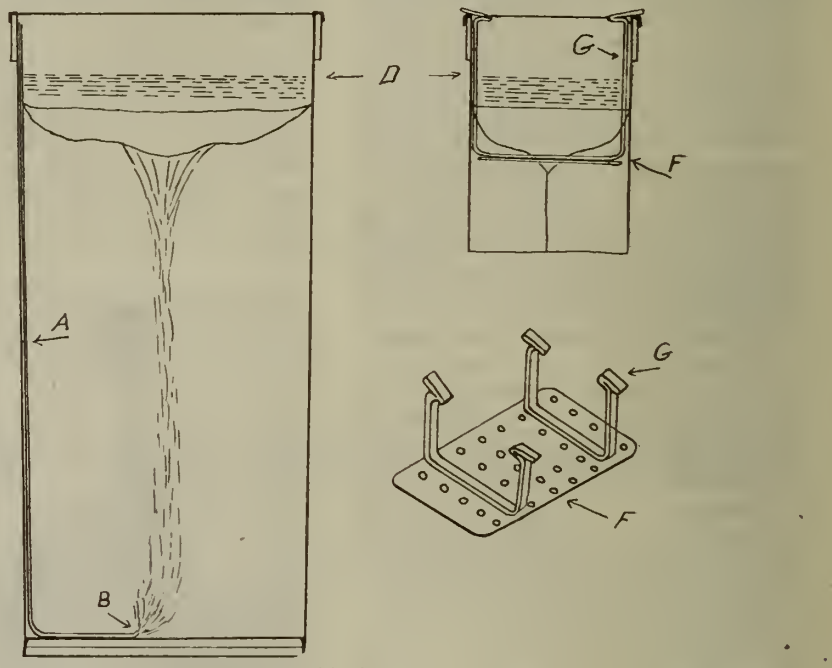


FIG. 2

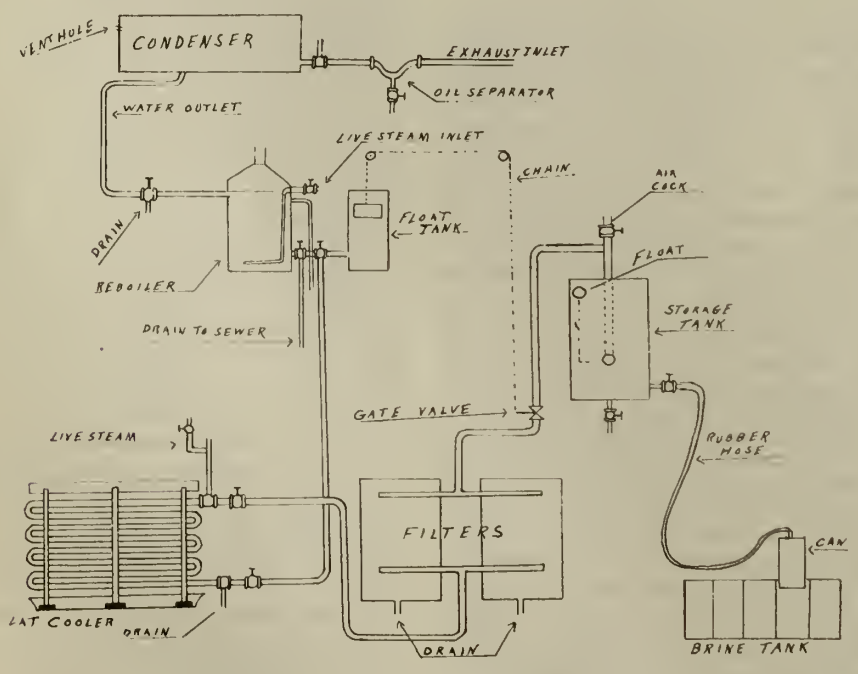

FIG. 1

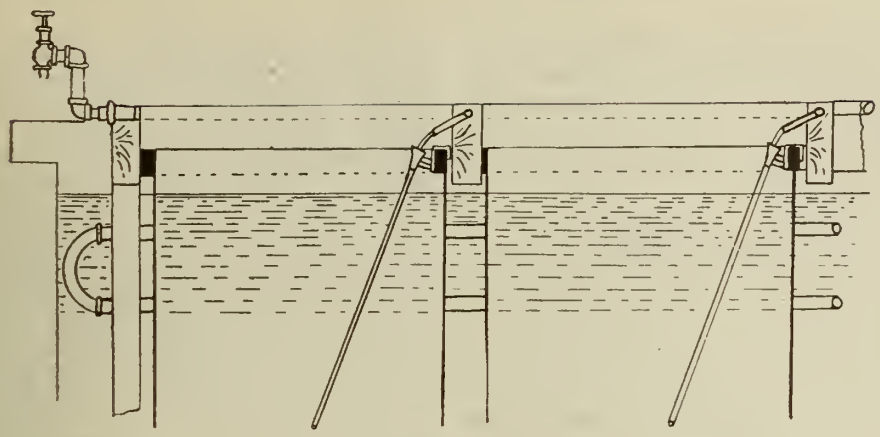

FIG. 3

the water between the cakes of ice until this water becomes so heavily charged with these impurities that it is necessary to drain it off and refill the space with fresh water. Practically all ordinary drinking water may be made into merchantable ice if properly filtered, and even in cases where the water is not drinkable the cost of the slight chemical treatment necessary is not prohibitive. The agitation of the water during the process of freezing is the key to the situation, as any method which will produce this motion of the water will produce marketable ice provided the water is not allowed to freeze while it is so full of impurities that they are frozen into the ice itself. If ordinary water is frozen in the can without treatment the result is a block of white opaque ice, this being due to the presence of air, but if the water is agitated during the freezing the small air bubbles are made to rise and do not cling to the surface of the growing ice.

There are several types of agitator on the market, and as may be expected, each type has its advocates, but in a general way, raw water plants may be classified as low or high pressure, with another special system which combines the two. The introduction of air at about 2 lbs. pressure is usually sufficient to agitate the water in the can, but during the process of freezing in this low pressure system, ice often collects at the end of the air tube and sometimes obstructs the passage.

The water in the centre of the can near the bottom is always the last to freeze, and in all systems the end of the air tube reaches that part, in some cases drop tubes being used, which hang over the can in a perpendicular position, while in other cases the pipe is led down the inside of the can as shown in Fig. 2. When this method is used it is not necessary to lift out the tube when the can is pulled and it is not in the way if it is necessary to pump out and refill the core, but the fact that the location of the pipe subjects the air passing through the tube to the brine temperature, causing freezing up, is a decided disadvantage. This frequently forces the installation of air coolers, which naturally add to the difficulties of running such a plant.

In Fig. 2 the air pipe can be seen at A, the air entering the water at B, passing upward along the surface of the ice as it forms, causing an agitation on all of the freezing surfaces which keeps the impurities from freezing into the ice. When the ice begins to close up, the air still blows upward between the surfaces until the space becomes so small that in many cases the remaining water is blown out into the unfrozen space above.

In other cases, the water between the freezing surfaces, after becoming heavily charged with impurities, is pumped out and the space refilled with pure

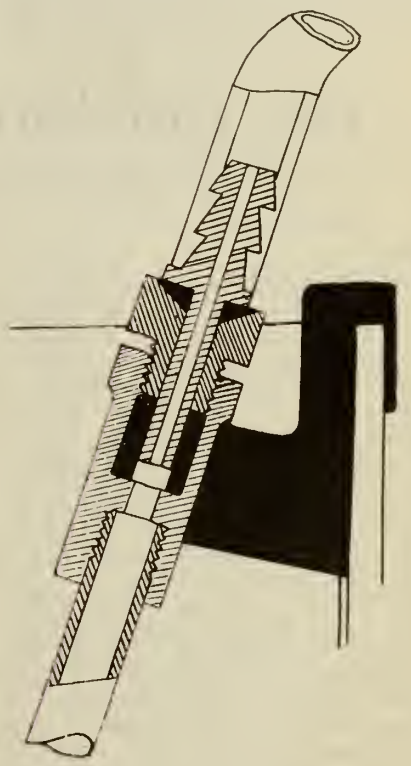

FIG. 4.

water. It may be noted, however, that if it is necessary to refill with distilled water, this necessitates a distilling plant of some sort, which is, of course, an added expense.

The space usually occupied by the unfrozen water is shown between the top of the ice block E, and the water level D. This water is usually thrown out when the can is pulled. Here again there is a disadvantage, as when the core is drawn and refilled, if distilled water is not used, the ordinary water may contain impurities and not being thoroughly agitated, they may freeze in the ice. In any event, cakes of uneven height are formed, and, to obviate this, grids as shown at F are used. These are perforated and are frozen into the ice at any desired height, being held by the straps G.

After the can has been pulled, the grid may be easily removed, together with the ice above it, but here again we

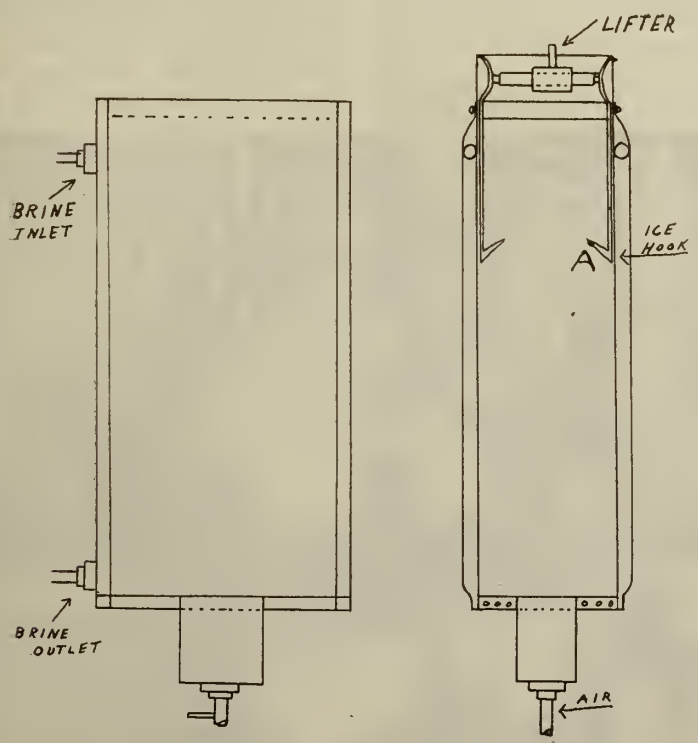

FIG. 5

have a waste of ice which has cost money. This is a serious matter, as in a plant of a hundred tons daily capacity, this loss might easily amount to several thousand dollars annually, as at least 5 per cent. of the product must be thrown away.

In Fig. 3 is shown what may be called a medium pressure system. The air tubes are suspended from the side of the can by a brass bracket and they extend diagonally down to a point near the bottom of the centre of the can. Both the bracket and air tubes are handled together, and when the can has been filled and lowered into place, the tube is easily hung on the side of the can.

The details of the tube and bracket are shown in Fig. 4. A permanent air pipe is placed between each two rows of cans, and supplies air to both sides. This pipe carries air at about 20 lbs. pressure, but as each nozzle contains a very small opening, just enough air escapes to properly agitate the water as there is a natural reduction in pressure. The moment, however, that ice forms around the end of the tube or there is any other obstruction, the pressure builds up until the air forces its way through and clears the passage.

The position of the tubes also serves to keep them surrounded with water at no more than 32 degs. Fahr. and therefore freezing of tubes does not occur.

When the can has been pulled, and it is necessary to remove the tube, the operator simply uses a thawing needle of very small diameter, which is pushed through the tube until it reaches the bottom, and by the time this is done, both tube and needle may be easily withdrawn.

The amount of steam used in this operation is very slight, and it can usually be completed in four or five seconds.

There are several systems on the market in which the agitation method is not used, one being shown in Fig. 5, a stationary double-walled can is used, cold brine circulating in the jacket space. A good brine circulation is insured by using from 5 to 10 lbs. pressure, and this gives a good heat exchange. The lower part of the tank is not in contact with the brine and therefore it is non-freezing. This lower part serves as a settlement place for the impurities which become concentrated as the freezing progresses. Hooks as shown at A, Fig. 5, are used in removing the ice cakes which have previously been thawed loose by a circulation of relatively warm brine in the jackets. This system is easily controlled, freezing is regular, but the ice is usually only semi-transparent, and not to be compared with that made by the agitation process.

The Installation of an Ammonia Compressor

The Following Article Describes a Recent Installation in Montreal in Which a Short Belt Drive Was Used With Good Results

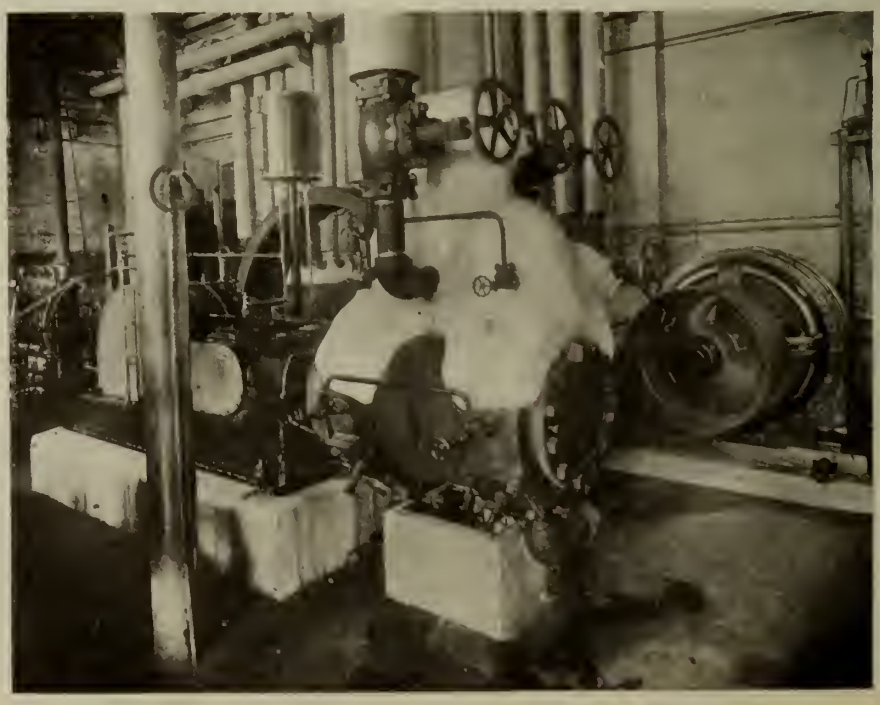
By J. H. RODGERS

HIGH speed ammonia compressors are by no means a new innovation to the artificial ice making or refrigerating industry, but their appearance in Canada is, virtually, of recent origin. The installation here illustrated is that installed last year at the plant of the Matthews-Blackwell Co., in Montreal. Lack of available floor space and the necessity of increased refrigeration were two of the main reasons for the decision to install one of these high speed machines. The unit here shown is a 50 ton De La Vergne high speed ammonia compressor, belt connected to a 200 h.p. Canadian General Electric motor. running at a speed of 600 r.p.m. The compressor operates at a speed of 149 r. p. m. The space occupied by this De La Vergne machine is less than the unit it displaced, and yet it has twice the capacity of the previous compressor. A feature of this installation is the comparatively short drive, the centre distance of the two shafts being only 9 feet; the respective diameters of the driving pulley and the compressor fly wheel being 31 inches and 8 feet. A skeleton sketch of the drive, together with the Lenix roller is here shown. With the exception of brief shutdowns, as a result of the power going off, this unit has been in continuous operation, night and day, for nearly twelve months.

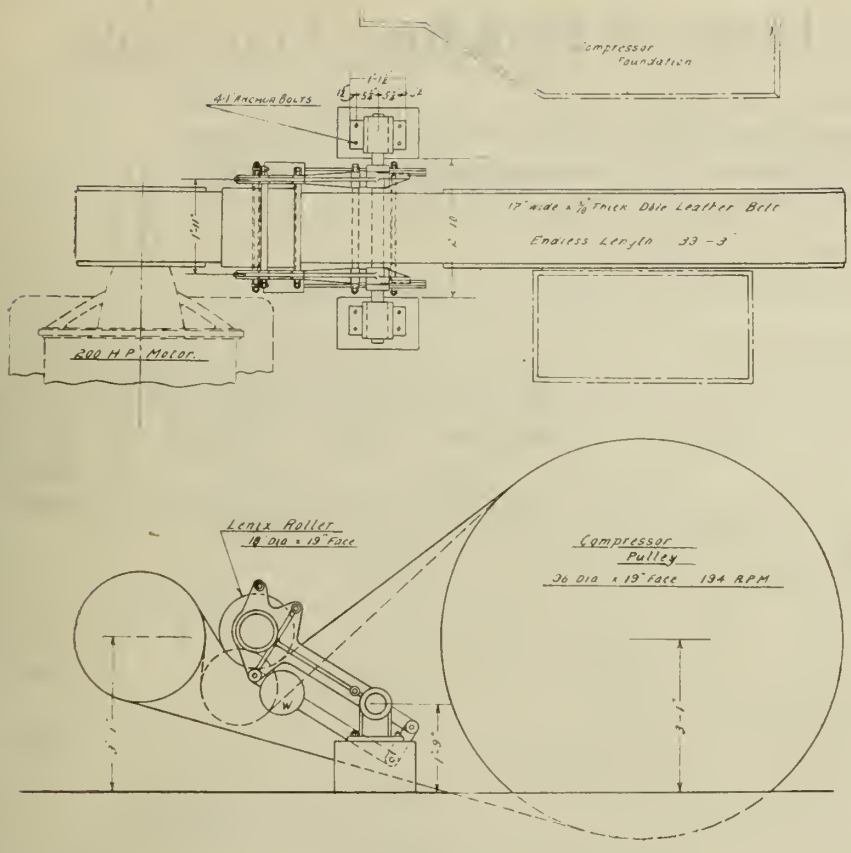
The following is a brief description of the machine: The frame of the compressor is of the tangye type and is designed for great stiffness, with large bearings for both crosshead and main bearings. Moving parts are enclosed in sheet metal guards, which may be easily removed and at the same time keep out dirt and saves the lubricating oil. There is an extension on the bottom of the frame, which rests on the foundation, giving added stiffness to the section under the main bearing. By grouting this extension firmly in the foundation, movement of the machine on the foundation is prevented. A large opening is left in the frame for ready access to the stuffing box. The stuffing box is an integral part of the front head, packed with a combination of special metallic and soft packing, containing a short lantern, which is connected to the suction line and into which the oil for lubricating the rod is pumped. The packing is held in place and adjusted by a screw gland.

The discharge ports and cylinder heads of the compressor are water-jacketed, but the suction ports and cylinder barrel are unjacketed because the water would heat instead of cool the incoming gas.

The main bearing is of the four part type. The cap is not babbitted, except at the end of the bearings, and then only to keep the oil from getting away, and to give a fixed point to which the shaft can be adjusted. The cap fits snugly between the jaws of the frame and is bolted down solidly on top of the jaws. Unlike all other bearing caps, it is not used in adjusting the bearing, as adjustment in a vertical position is made by a wedge under the bottom shell. In making up for wear, every adjustment brings the shaft back to the original position as fixed by the cap. Only one wedge is used for side adjustment, which construction was adopted because of the fact that the bottom shell follows the shaft in its motion. If adjustment in the other direction is necessary



DE LA VERGNE ICE COMPRESSOR WITH SHORT BELT DRIVE.



DETAILS OF BELT DRIVE.

shims can easily be placed back of the stationary quarter box. The adjustment in one direction only prevents the shaft from being moved out of line.

The connecting rods and cross head have few special features, except the method of lubricating the crosshead pin. A hole is drilled lengthwise through the centre of the connecting rod and connects with holes in crankpin and crosshead pin boxes. Special oil grooves are cut in the crankpin box, and the oil is forced by centrifugal force and inertia to the crosshead pin. This does away with one of the greatest difficulties to be overcome in the lubrication of a compressor. Other methods are unsatisfactory, due either to the necessity of catching drops of oil while in motion or to a multiplicity of small wearing parts which easily get out of order and cause shutdowns. On account of the large diameter of the crankpin and the shaft, it is deemed advisable to make the crank and crankpin in one piece, a steel casting, which includes also the necessary counterweight to balance the reciprocating parts.

Oil for lubricating all bearings and guides is collected in the base of the frame and is removed from there by a small geared pump, driven by a belt from the main shaft. The oil is then passed through a filter, mounted on the frame, and is returned free from grit, dirt and water, to the points of lubrication, namely, two on the main bearings, one on the crosshead guide, and one from which both the crosshead pins and crank are lubricated. The lubricator for the stuffing box is mounted on the same bracket with the oil pump, and is driven by a belt. These auxiliaries are belt driven so that in case of trouble the belts can be thrown off and the pump and lubricator repaired, replaced and put in operation again without necessitating a shutdown of the compressor. A hand-pump for cylinder lubrication is also provided, and the filter contains enough oil to last for at least one-half hour, thus giving plenty of time for repair. The only part of this machine which is made fast to the foundation is the frame; the cylinder is merely supported and is free to move, thus taking care of contraction and expansion, and the deflections due to pressure changes.

SUFFICIENT POWER FOR TWENTY CITIES

Southern British Columbia is Rich in Important Water Powers

In British Columbia there are many important water powers. The investigation of the water powers of British Columbia by the Commission of Conservation has disclosed the existence of two great water power centres, namely, Nelson, with 400,000 h. p. within a radius of 50 miles, and Vancouver, with 300,000 h. p. within the same distance. Based on experience at Toronto, these quantities would suffice for a population of 1,700,000 at Nelson, or for 10 manufacturing cities of 170,000 each. The power near Vancouver would suffice for one manufacturing city of 1,250,000 population, or for 10 cities of 125,000 each.

There are 12 power sites in British Columbia of 50,000 h.p. and upwards. With the exception of the South Fork Quesnel and Peace River, all these powers are less than 125 miles from the 49th parallel.

	h. p.
Kootenay River, Upper and Lower Bonnington Falls, possible development	125,000
Pend d'Oreille River, Waneta	73,000
Pend d'Oreille River, Salmon River	50,000
*Thompson River	100,000
*Fraser River, Hellgate	200,000

Nass River, falls below Cranberry low White River	20,000

There are 29 power sites of between 10,000 and 20,000 h.p. capacity and 585 of less than 10,000 h. p. The report of the Commission of Conservation on the water powers of British Columbia includes all vailable data respecting 644 water power sites.—James White.

*Development debarred owing to presence of railways.

German textile industries not only used paper as a substitute for wool and cotton but also made great use of hair, human and from dogs and other animals. Great hopes were based on a scheme for the breeding of rabbits of the white silken-haired variety, but nothing was done as presumably rabbits made good stew or pie. The scheme which may yet be carried out involved the breeding of several million rabbits. The hair may be spun into very fine and soft threads.

Heat Transfer Tests of Building Materials

The Following Article, Reprinted From the Journal of the Engineering Institute of Canada, December Number, Gives Some Interesting Results of Tests on the Transmission of Heat Through Various Types of Building Materials

By L. M. ARKLEY, M.E.I.C.
Assistant Professor of Mechanical Engineering, University of Toronto.

IN 1912 the following series of tests were started at the request of the Department of the Provincial Secretary of the Ontario Government, for the purpose of assisting in the selection of the proper materials to be used in buildings in course of erection at that time by the Department. The general method of making the tests was decided at a conference including Professor Angus, of the University of Toronto, Capt. R. J. Durly, M.E.I.C., consulting engineer to the Ontario Government; James Govan, architect of the department of the Provincial Government, and the writer.

In 1913 another set of tests was authorized to determine the effect of the transfer of heat through a 12 inch hollow tile wall of laying it up, first with the hollow spaces horizontal, and second with the hollow spaces vertical and directly over each other.

And in 1914 a third set of tests was required to investigate the heat insulating qualities of a number of materials which might be used in the walls of refrigerating rooms.

The apparatus shown in Figures 1 and 3 was installed in the Thermodynamic laboratory of the University of Toronto, in order to carry out these tests.

Object of Tests Made in 1912

To compare the insulating values of walls of approximately equal thickness, but built of different materials, viz.:

8 inch hollow concrete block.
9 inch brick wall.
7 3-4 inch hollow tile.

And further to determine the effect in insulating value of plastering the walls and of stopping air circulation in the hollow walls by filling the spaces with cheap materials, or by using paper on the inside of the walls.

The most common methods that have been employed in making such tests are as follows:

(1) A box is made of the material to be tested; inside the box is placed a vessel containing a weighed quantity of hot water at a known temperature (the water must be agitated in order to get the true average) by taking the temperature after a certain time the b.t.u. loss may be approximately computed.

(2) The same arrangement is used as in method No. 1, but a weighed quantity of ice is used instead of the hot water, and the b. t. u's transmitted computed from the weight of ice melted in a certain time.

(3) An electric heater made of fine resistance wire, wound on an electrically insulated sheet is imbedded in the material to be tested and the b.t.u's computed from the electrical energy supplied to the heater in a given time.

A box is built of the material to be tested, and the heat is supplied to the inside of this box by means of an electric heater. This box is placed in a room which is kept at a low temperature by means of a refrigerating machine. By measuring

Feb. 19	12	Hollow tile without plaster. Air spaces filled with gravel	71.3	71.82	22.75	102.32	20.05	0.355

the current and temperature inside and outside the box the b.t.u. loss may be computed.

The main objection to the first three methods mentioned is that they do not represent conditions found in practice, and from the nature of methods No. 1 and No. 2 it is almost impossible to get accurate results.

In most cases in practice either in dealing with heating problems or problems in refrigeration the medium of transfer of heat is air, and air usually in motion, so that in choosing a method for making these tests a modification of method No. 4 was decided upon, but instead of using a box it was decided to use a wall whose area could be measured directly. See sketch No. 1.

Arrangement of Wall and Instruments in Making Tests

By referring to sketch No. 1 the arrangement of the testing apparatus will be seen. A box was made of ⅞ inch T. and G. sheeting supported by 2x4 in. scantling, and held together by steel angle braces and bolts. This box was lined with two 2 in. layers of pressed cork held together by wooden pegs, all joints were carefully broken and a sheet of waterproof paper was placed between the layers of cork. The inside of the box was finished with a coat of asphalt paint.

Into this box, which is a very good heat insulator, the wall or material to be tested was built in such a manner as to divide the box into two compartments. When the wall to be tested was in place the cover ends and sides of the box were firmly drawn together by means of bolts. One of these compartments communicated direct with the cold room of a 3-ton refrigerating machine, and in this way a temperature of 20 degrees F. or lower if desired, was easily maintained. On the opposite side of the wall heat was supplied by means of an electric heater made of resistance wire strung on a 3x3 ft. frame, a bank of lamps and a rheostat placed in the circuit supplying the heater allowed any desired quantity of heat to be supplied.

To get the average temperature on each side of the wall four thermometers were suspended from the roof of the box, two on the cold side and two on the hot. When readings were required these thermometers were partially withdrawn through small openings in the covers, but the bulb of the thermometer was never exposed to the room temperature. These thermometers indicated the necessity of circulating the air on each side of the wall in order to get a uniform temperature, and two small electric fans were placed, one on each side of the wall inside the box to give the required circulation. The electric current being supplied to the heater and fan was measured by

means of an accurately calibrated voltmeter and ammeter.

Method of Conducting Test

The refrigerating machine and fans were operated until the temperatures on each side of the wall remained constant. This indicated that all the heat being put into the high temperature side of the box was being transferred through the wall. After this state had been reached a run of about an hour's duration was made, while readings of temperature, amperes and volts were taken every ten minutes.

Method of Making Calculations

As an example we will work out the value found in test No. 1 on log. sheet page 7.

1 watt = .0009477 B.t.u's per sec.
1 watt = 3.41172 B.t.u's per hr.
Watts = Amperes × volts
" = .647 × 227.7 = 147.32 used by heater.
" = .240 × 113.8 = 27.31 used by fan.
Total watts used = 174.63

B.t.u's per sq. ft, per hr. =

$$\frac{174.63 \times 3.41172}{19.65 \times 48.1} = 0.63$$

per degree diff. of temperature.

Possible Errors in the Above Method

(1) Leakage of heat from the high temperature side of box to the surrounding air or vice versa.

From the dimensions of the box it will be seen that the surface exposed to such a loss is about 26 square feet.

A liberal value for the heat loss in B.t.u's per square foot per hour per degree difference of temperature for the box is .0875.

Assuming a difference of temperature between the room and high temperature side in box of 1½° the heat loss per hour would be:

$26 \times .0875 \times 1.5 =$ B.t.u. per hr. $= 3.4$

This value is so small as to be negligible for practical purposes.

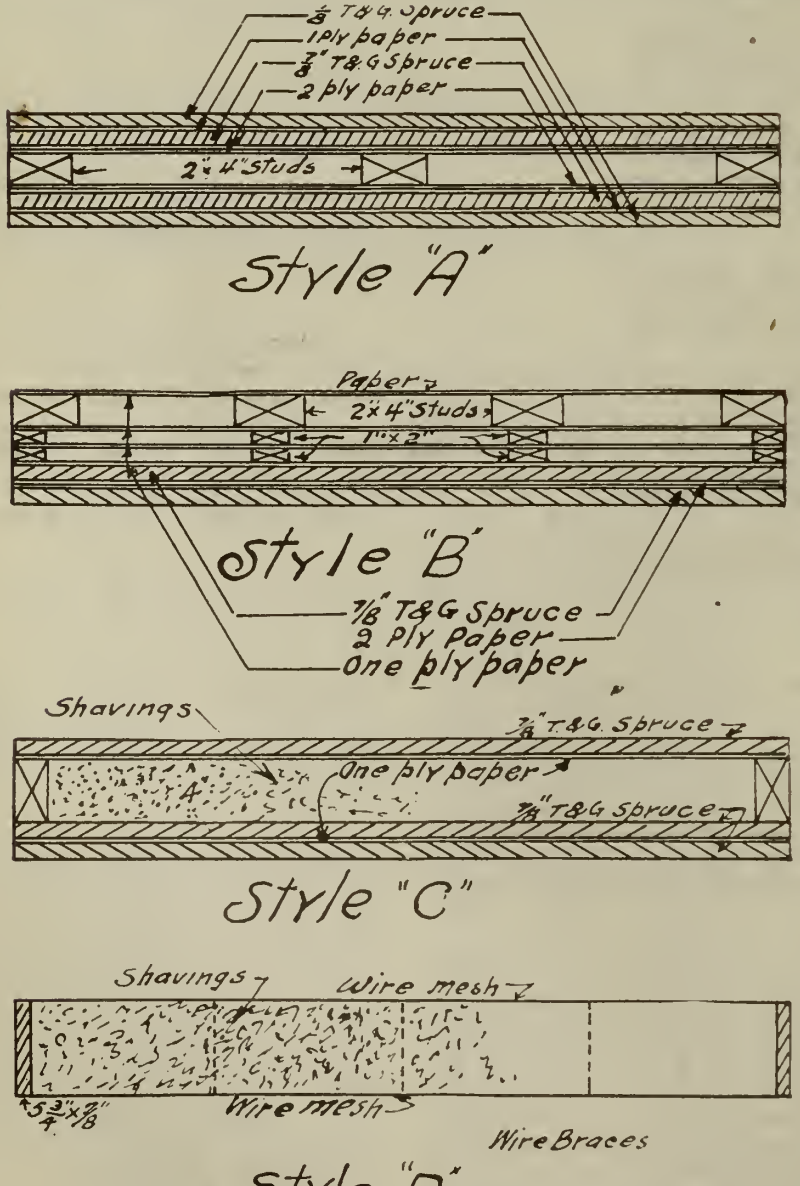
In order that there might be little loss from this source the temperature of the room was kept as near 70° Fahr. as possible. In most cases the difference between the room temperature and that inside the box on the high temperature side of wall was much less than 1½°. The range of temperature decided on for the tests was from 70° Fahr. on hot side to 20° Fahr. on cold side, giving a temperature of 50° Fahr.

(2) Possible error due to length of run.

The accuracy of the method employed in making these tests depends on the length of run being sufficient to allow the heat to permeate the wall and the heat gradient to be established. This is indicated by the temperature on both sides of the wall becoming constant; until this point is reached it would not be correct to assume that all heat being supplied was passing through the wall.

In testing the hollow walls with spaces vertical a good check on this point was obtained by inserting a thermometer through the box cover into the centre of the wall. When the thermometers on the high and low temperature sides of the wall showed a stationary condition the thermometer in the centre indicated very nearly the mean of the other two readings.

As stated in the beginning of this report, three series of tests were made, in 1912-13 and 1914 and the report is therefore divided into 3 parts: descriptions of the walls tested, specifications for plastering and log sheets of tests follow each part.



TYPES OF WALLS TESTED

Tests Made in 1912

Description of materials used in walls tested:

Concrete Blocks.—For dimensions see sketch No. 1.

Composition: One bag cement to four cubic feet of sand and one cubic foot of ¾ in. crushed stone, with ¼ in. and all below screened out.

Age: About two months. Weighs 38½ lbs. Weight of water absorbed per block after being submerged twenty-four hours, 3¾ lbs.

Tile.—For dimensions see Sketch No. 1.

Dry weight of tile 30¾ lbs. Weight of water absorbed per block after being submerged twenty-four hours, 3½ lbs.

Brick.—Hard burned common brick, dimensions 2½ in. x 4¼ in. x 8½ in.

Weight dry = 4.67 lbs. Weight of water absorbed per brick after being submerged twenty-four hours, 1.125 lbs.

Flooring felt used in test No. 6, actual weight per 100 square feet—11.5 lbs.

Tarred felt used in test No. 7, known as 16 oz. felt, actual weight per 100 square feet—25 lbs.

Asphalt felt used in test No. 8, known as Neponsit, Asphalt felt.

Specification of the construction and finish of walls to be built at Thermodynamics Building, University of Toronto, for thermal-conductivity tests by James Govan, architect.

Test No. 1—Tile Wall

Tiles to be used.—Wall to be built of 8 in x 8 in. x 16 in. concrete hollow wall tiles.

Mortar.—Mortar for building tile to

LOG SHEET OF RESULTS TESTS MADE IN 1913

Date	No. of test	CONDITIONS	Average Temperature			Total watts	Sq. ft. of wall surface	B.T.U's transfer per degree diff. of temper. hr. per sq. ft.
			Room	High side	Low side			
1913 Dec. 16	1	12″ tile wall laid with hollow spaces horizontal	70.7	71.75	20.9	91.78	20.91	295
Dec. 17	2	12″ tile wall as above but with 1 layer of paper on high temp. side of wall	70.6	69.55	19.	6.5	20.91	210
Dec. 18	3	12″ tile wall as above with paper removed and 1 coat of dehydratine painted on high temp. side of wall	70.	70.13	19.9	63.75	20.91	206
Dec. 25	4	12″ wall as above but plastered both sides, plaster ⅝″ thick	65	67	18.25	53.75	20.91	179
Feb. 27	5	New 12″ tile wall built with hollow spaces vertical and directly over each other	72	70	20.4	99.7	21.28	322
Mar. 2	6	12″ wall as above with one coat of dehydratine on high temp. side	69.5	69.25	20.45	76.4	21.28	250
Mar. 9	7	12″ wall as above but plastered both sides, plaster ⅝″ thick	73.3	70	20.8	69.97	21.28	228

be composed one part lime to three parts of good clean sharp sand.

Joints.—Joints to be ⅜ in. wide. Tiles to be wetted before laying to prevent absorption of water from mortar.

Furring strips.—Provide and build into side of wall away from refrigerator at every second joint, wood furring strips ⅜ in. x 1¼ in. for wood strapping.

Strapping.—Strap this side of wall with wood straps at 12 in. centres.

Metal lath.—Metal lath for plastering to be expanded metal No. 24 gauge.

Plastering. — Plastering on this side of wall to be three coat work composed as follows:

1st coat.—One part alca and lime mixture as supplied.
Three parts sand.
Fibering material or hair as required.
This coat to be thoroughly scratched.

2nd coat.—One part alca and lime mixture.
Four parts sand.
Fibering material as required.

Finishing coat.—One part alca and lime mixture.
One part fine white sand, trowelled to a smooth polished surface.

Stucco on side of wall next refrigerator.—Base coat shall be applied direct to the tile wall and shall consist of one part alca and plaster mixture to four parts sand. Surface of tile wall must be thoroughly wetted before this base coat is applied and the mortar scratched in preparation for the second coat.

Second coat to be composed of one part alca and plaster mixture, to four and one-half parts sand, trowelled smooth.

The second coat must be applied before the first coat is allowed to dry out.

Test No. 2—Brick Wall

Bricks.—Bricks to be good, common stock bricks, approved of by the architect.

Mortar.—Mortar for building bricks to be composed of 1 part lime to 3 parts clean, sharp sand.

Joints to be ⅜ in. thick and struck on both sides of wall. Bricks to be thoroughly wetted before laying.

No plastering inside or outside of wall.

Note: There will be no plastering on either inside or outside of brick wall for this test.

Conclusions

The most important conclusion to be drawn from the above results is that the commonly held assumption that a hollow block wall is more efficient from a heat loss standpoint than a solid brick wall of approximately equal commercial standard thickness is not founded on fact. This will be clearly seen by comparing tests Nos. 1, 9, 10 and 11. On the other hand tests Nos. 2, 3, 5 and 12 show that if the spaces in the hollow block wall are filled with some material which separates the air into small pockets and prevents circulation that the rate of transfer of heat is considerably diminished.

An interesting result is shown by comparing test No. 4 with No. 7. The conditions in these tests are exactly the same with the exception that one layer of tarred building paper was placed on the high temperature side of the wall in test No. 7, the effect of this layer of paper was to reduce the heat transfer by nearly 50 per cent.

Tests Nos. 9 and 10 serve as a check on the work, as many tests have been made on 9 in. brick walls and the commonly accepted value as the coefficient of conductivity is 0.4 B.t.u.

It may be mentioned that in having the brick wall built, the architect took special pains to see that the laying of the bricks was no better than the ordinary standard of bricklayers' practice. No attempt was made to have all points in the interior of the wall filled and the face jointing was struck with the trowel as the wall was laid up. If the bricklayer had been allowed to fill carefully every joint with mortar and to have the wall so well flushed as to reduce air circulation through the wall to a minimum, better results would no doubt have been obtained. On the other hand in building 7¾ in. hollow tile wall the practice adopted was decidedly better than would obtain in ordinary contract work.

Where hollow tiles are laid with webs vertical it is practically impossible to get the bricklayers to spread mortar on all webs of the tile. As a rule the two outside and the two end webs receive mortar, while the interior webs are left uncovered. In the wall tested every web was carefully covered and every precaution taken to keep the air spaces free.

When the wall was built the outside and inside face joints were carefully pointed up so as to reduce air circulation through the joints to a minimum. Under these conditions the results obtained are probably more favorable to the hollow tile wall than they would be in ordinary construction practice.

Note: Sawdust was not used as filling with the idea that it would be a suitable material for building construction but simply to show the effect of breaking

up the circulation of the air in a hollow block wall.

Tests Made in 1913

Object of Tests.—(a) To determine the rate of transfer of heat through a 12 in. hollow tile wall, first when the tile was laid with the hollow spaces horizontal; second when the tile was laid with the hollow spaces vertical and directly over each other.

(b) To determine the effect on the rate of transfer of heat of placing a layer of ordinary building paper on the high temperature side of wall.

(c) To determine the effect on the rate of transfer of heat of painting the high temperature side of the wall with one coat of "dehydratine."

Materials Used in Walls

Tile.—The hollow tile used was a shale tile made at the Ontario Government's clay plant at Mimico, Ont. For dimensions, see Sketch No. 1.

"Dehydratine." — Described by the manufacturers as a "Foundation compound for waterproofing substructures."

It has about the consistency of the ordinary ready-mixed paint, is black in color and is made up principally of asphalt

These tests were made in the same manner as those previously described in this report and the specifications for plastering are the same for both series of tests.

Conclusions

Comparing tests No. 1 and No. 2 the marked improvement in the insulating

The composition of the asbestos products is approximately 15% asbestos and 85% portland cement.

qualities of a layer of paper is again demonstrated.

From test No. 3 it would appear that one coat of "dehydratine" accomplishes practically the same result as a layer of paper. This is what might be expected, as both the paper and "dehydratine" serve to close the pores in the wall.

Comparing test No. 1 with No. 6, we see that the wall is a better heat insulator when the hollow spaces in the tile run horizontally than when they are vertical. In the second case the circulation of air would be much more pronounced due to the chimney effect of the vertical hollow spaces.

Comparing tests Nos. 1 and 3 with Nos. 6 and 7, approximately the same saving is shown due to one coat of "dehydratine."

Comparison of the results obtained with walls plastered and without plaster show that plaster is not a good heat insulator.

Tests Made in 1914

Objects of Tests.—To determine the rate of transfer of heat through walls suitable for refrigerating rooms, including built-up walls (for details see Sketch No. 2), cork walls, and ordinary building papers.

Materials used.—Paper used in test No. 1—oiled paper—thickness 10/1000 of an inch, weight per square foot—5¼ pounds.

Paper used in test No. 2—trade name "Climax"—sat-building paper, advertised as acid, salt, alkali and waterproof, thickness 18/1000 of an inch, weight per 100 sq. feet = 10.4 pounds.

Test No. 3 was made to test a wall of planer shavings 6 in. thick. A frame 6 in. deep shown on sketch No. 3 as style D was made of ⅞ in. boards. A fire screen, 12 mesh to the inch, was fastened to each side of the frame and shavings packed between the screens, giving a wall of shavings 6 in. thick.

For details of walls used in tests No. 4, No. 5 and No. 6, see sketch No. 2.

Cork walls used in tests No. 8, No. 9 and No. 10 were made of slabs of pressed cork, 1½ in. thick x 12 in. wide x 3 ft. long.

We wish to acknowledge assistance given by Professor Angus, of the Mechanical Engineering Department, University of Toronto; James Govan, architect, Department of the Provincial Secretary of the Ontario Government, and the Asbestos Manufacturing Co., of Montreal, which furnished the asbestos products tested.

THE PROPER SIZE OF FUSES FOR INDUSTRIAL MOTORS

THE proper size of fuse for a motor is only too often obtained by the chief electrician or one of his repairmen by haphazard methods. The motor's normal operating current is given by the maker on the name-plate, but fuses are properly selected of a larger capacity to allow for starting and for momentary overloads. Hence it is rather more unual for the maintenance man to select his fuses "be guess and be gosh," with a view to their permanence in service rather than the safety of the motor they are supposed to protect.

In order to give a practical working idea of what sizes to use, the Westinghouse Electric & Mfg. Company has prepared the accompanying tables. These are based on the following assumptions as to size of fuse required to stand starting current without blowing:

Type	Time fuse load Current at starting
Polyphase wound rotor	1–¼
Squirrel cage (thrown on line)	3
Single-phase repulsion induction with rheostat	2
Single-phase repulsion induction without rheostat	4
Direct current	1–¼

Since the fuses for squirrel-cage and repulsion motors without rheostats are, respectively, rated at 3 and 4 times full-load current, they give practically no overload protection. Hence it is recommended that double-throw switches be installed connecting the motor through fuses of 1.25 times full-load rating (as under wound rotor sizes) for running and through the regular heavier fuses or direct to the line for starting.

VOORHEES RUB-STEEL VALVE

Owing to the isolated nature of steamship operation during long journeys it is of the utmost importance that the engineering equipment be of first-class quality, assuring continuous operation under the most severe service. Valve maintenance is an essential detail of engineering efficiency. Leaky pump valves are frequently a source of great annoyance to the operator, and expense to the owner.

The Voorhees Rub-Steel Valve is made in four different grades. Standard, for service under moderate temperatures up

RUB-STEEL VALVE

to about 160 degrees. Superhot, for use on equipment adapted for hot oil, etc., where temperature exceeds 160 degrees. Special soft, for low pressure water service, slightly gritty fluids, etc. Red condenser, for service under specially severe conditions. These valve discs are made in a large variety of sizes and for any particular purpose. As the name implies the valve is made of a combination of rubber and steel; the rubber composition attached to the central steel disc by a special electrochemical process known as the Elchemco process. The steel plate adds great strength to the valve and prevents distortion under high pressure, while the rubber assures perfect contact with the seat. This construction increases the average life of the valve, eliminating the possibility of destruction by forcing through the grating or breaking up into pieces. Reliable service is an economic necessity in steamship operation.

MEDIUM SPEED HORIZONTAL AMMONIA COMPRESSORS

THE high cost of labor, machinery, fuel and in fact all other things that pertain to the building and operating of an ice or refrigerating plant, have led the manufacturers of such apparatus to secure the highest economy possible.

This article will be confined entirely to the medium speed horizontal machine as shown in Fig. 1, which is built in three types, one for belt drive, another for direct connecting to a synchronous motor which is mounted on the shaft beside the fly wheel and the other direct connected to a uni-flow poppet valve steam engine. This machine in any case is of the same construction with the exception of the crank shaft which is made to suit any particular installation. As the majority of people are familiar with motor installations, this article will treat only of the engine driven outfit.

The manufacturers of the machines illustrated, The Frick Company, Inc., Waynesboro, Pa., U.S.A., build both vertical and horizontal, slow and medium speed compression machines, ammonia absorption outfits and carbon-dioxide machinery. The ammonia compression and carbon-dioxide types are made in both the land type and the marine type, especially designed to meet the inspection of the various bureaus and registers of shipping.

The compressor frame is of the heavy duty, Tangye type and is of a one-piece casting. The cylinder end of the frame is bored and faced true with the cross head guides to receive the ammonia cylinder shell which is made of a special close grained iron. Between the outside of the ammonia cylinder and the inner shell of the main frame is an opening which is used for the water jacket, the water being delivered into the bottom and discharged at the top. The ammonia cylinder heads are made of a special Maypul steel and secured to the face of the cylinder by long steel bolts passing through the water space with a nut on the outside of each cylinder head.

The suction and discharge valves are arranged in the cylinder heads. Two horizontal suction valves are located at each end at the top and four discharge valves are placed radial in the lower half of these cylinder heads. The cages forming the valve seats and the valves are of a special forged steel having ample area to insure the ammonia cylinder of filling with gas at each stroke and also providing ample area for discharging the gas into the compression side of the system. Both the suction and discharge valves are designed so as to prevent them from getting into the ammonia cylinder by failure of a stem, and in case of an examination it is only necessary to remove the cover plate over the valve chamber. The valve and cage can then be drawn out.

The ammonia piston has spherical ends which are turned to a radius conforming to that of the heads. The design permits the clearance to be reduced to a minimum. The piston is provided with four spring packing rings placed in suitable grooves and fitted carefully to prevent leakage. The piston rod is of forged steel pressed into the piston head and followed and secured by a doweled lock which is finished off even with the piston head.

The ammonia stuffing box is made very long compared with the diameter of the piston rod and in the bottom of the packing box is a babbitted ring closely fitted to the piston rod. There are two sets of packing used, separated by an oil lantern which is at all times filled with oil surrounding the piston rod. With the construction used, it is not necessary to draw the packing down hard to prevent leaks. This, of course, means that unnecessary friction and wear on the piston and packing is eliminated.

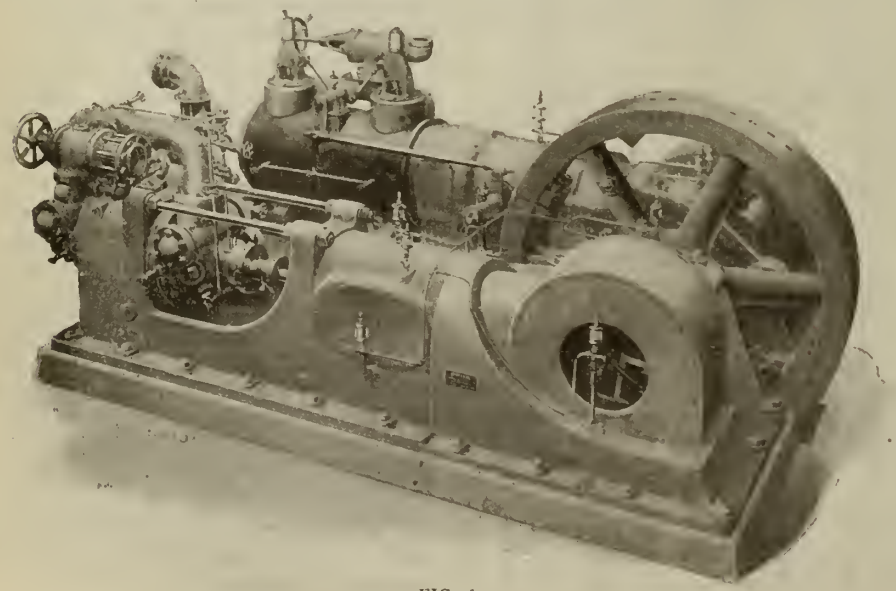

FIG. 1

The conduits or manifolds connecting the suction and discharge nozzles of the cylinder heads have long radius bends giving an easy flow of gas and are provided with purge and pump-out connections. A very fine mesh wire screen inserted in the suction trap near the nozzles of the suction manifold prevents all the foreign matter from entering the ammonia compressor valves and cylinder.

The cross head is of box form, designed for strength. The shoes have a large bearing surface of the best grade babbitt metal and are adjustable by means of wedges and screws.

The cross head pin is of special forged steel accurately ground to size and has taper fits in the cross head.

The connecting rod is of a rectangular section, forged from a solid steel billet. The stub ends are mortised at both crank and cross head ends to receive the bronze boxes which are lined with genuine babbitt metal. Adjustment at both ends is by means of steel wedges and large wedge bolts or lock screws. The wedges are so arranged that the length of the rod centres do not change when adjustment is made. The cross head and crank pin boxes are very large in proportion to the work they have to perform, thus reducing heating and wear to a minimum. The crank pin box is so designed that it may be removed without taking the connecting rod off the crank pin.

Crank shaft bearing is cast to the main frame and accurately machined and lined at right angles with the centre line of the cross head end and cylinder. The main bearing shells are extremely heavy and the side or cheek shells are adjustable for wear by wedges and special screws which lock them in position. The main bearing cap can be removed without disturbing the adjustment of the cheek shells. The bottom shell may be removed by raising the crank shaft a small distance. The bearings are generously proportioned and lined with genuine babbitt metal.

The steam engine is of the poppet valve, uni-flow type. The bed consists of a one-piece casting, comprising the main journal and the cross head guide. The general design of the engine bed conforms to that of the ammonia compressor and is of heavy duty Tangye type. The special feature is that all of the main bearing parts are identified with that of the compressor and are interchangeable. The cross head and the connecting rods are also the same as those of the ammonia compressor. In fact wherever possible without sacrificing design it is the aim to make the parts interchangeable.

The steam cylinder is of the uni-flow design with balanced double-seated poppet valves which are made of a hard, close grained metal, especially adapted for minimum wear after long service.

The valve chambers are located on the top of the steam cylinder near the ends and connected by special manifolds. The steam valve cages are fitted into these chambers, resting on ground joints. The valve cages contain the valve seats and

the valves which are carefully ground with the corresponding seats in the valve cages. The valves are actuated by cams lifting them vertically off the seats. The cam mechanism is properly designed and carefully machined to avoid all possible jar or shock to the valve and the seat when operating at medium speed. Special care in the design has been exercised so as to avoid sharp corners, restricted areas in the ports and warping of the valves and cages.

After cut off and expansion has taken place, the steam is exhausted through suitable ports arranged diametrically around the centre of the steam cylinder. These ports are uncovered by the steam piston at the end of the stroke, and the steam is exhausted into the exhaust chamber, thence it passes through the exhaust pipe to the condenser or atmosphere.

The steam cylinder is provided with an expansion chamber and valve at each end. If for some reason the vacuum in the condenser should fail, these valves are open and relieve the cylinder from an over amount of compression pressure. This valve also operates when running non-condenser.

The steam piston is of the single-piece, hollow design, made as light as possible consistent with strength. Six grooves are turned in the circumference, three near each end into which self-adjusting spring rings are fitted.

The governor is of the inertia type attached to the fly wheel and consisting of a pendulum which is pivoted to the arm of the wheel and carries the eccentric, a balancing weight, links and leaf spring. The balancing weights are made in a series of disks, so that they may be removed or the number increased as conditions may require. The spring has a wide range of adjustment and consequently can be adjusted for a wide range of speed.

All bearings, pins and cross head guides of both compressor and engine are lubricated by a gravity oiling system. Special provisions are made for collecting the oil and returning it through a filter to the gravity tank to be used over.

All parts such as valves, valve cages and steam piston receive heat treatment after they are rough turned, and then finished. The operating cams, rollers and valve gear pins and bushings are of steel, carefully case hardened and accurately ground to size.

When this unit is installed for marine service a heavy cast iron sub-base is furnished to which the compressor and engine is securely bolted with fitted bolts in reamed holes. This same sub-base can be furnished for land service if desired.

Figures 2 and 3 show illustrations of the vertical enclosed and vertical open type machines respectively.

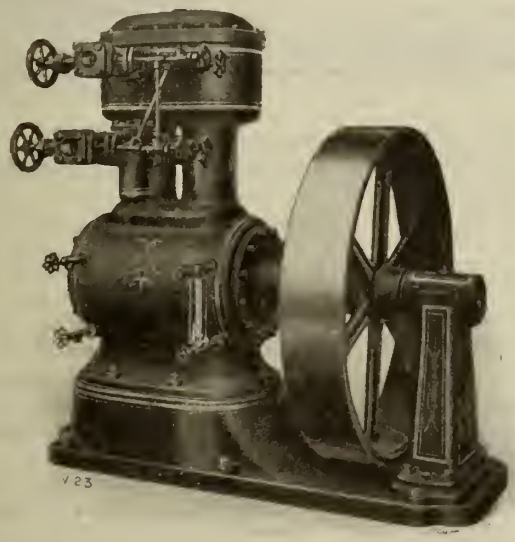

FIG. 2.

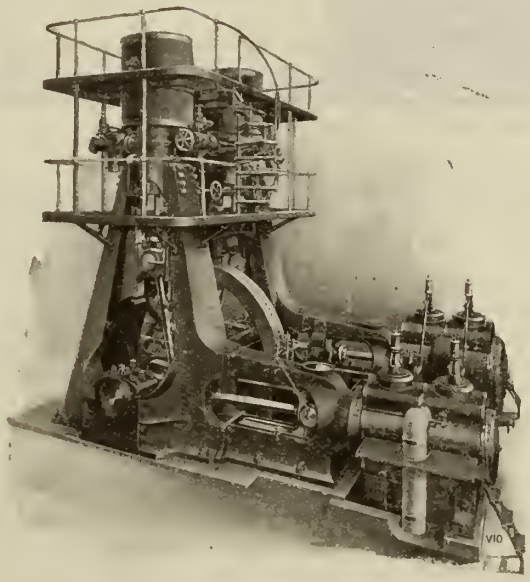

FIG. 3.

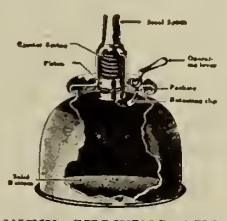
FORCE FEED OIL CAN

The accompanying illustrations show a new oil can developed by Gustave Lidseen, Desplaines street, Chicago. The mechanism controlling the feeding of oil is all in the spout and its arrangement is such that it will entirely empty the can. The oil can spout is self cleaning, and is easy to operate. The drawn steel body and heavy welded spout make the can leakproof. The spout is held on the can body by means of curved flanges with a packing ring held in the spout flange.

The can has a large opening and is therefore easy to fill and having a positive force feed is self cleansing and requires no spring bottom.



INTERIOR VIEW SHOWING SIMPLICITY IN CONSTRUCTION

SHOWING WIDE OPENING FOR FILLING ALSO CURVED FLANGES AND LOCKING MEMBERS WHICH MAKES IT LEAK AND WEAR PROOF AT THIS CONNECTION.

R. M. Wilson, M.E.I.C., chief engineer of the Montreal Light, Heat and Power Co., at a recent meeting of the local branch of the Engineering Institute of Canada, read a paper that dealt with the ice problems in connection with the operation of Hydro-Electric power plants. He described in detail the methods for dealing with ice troubles at the Cedars plant. With experience and improved design of hydraulic equipment, Mr. Wilson believes that machinery can now be designed that will be immune from ice troubles, excepting, perhaps, only those depending on canals running across country, where means cannot be taken to mitigate or eliminate the difficulties.

Winnipeg.—The last gap in the Shoal Lake to Winnipeg pipe line has been closed. Within the next few days Shoal Lake water will be pouring through the big pipe and into Winnipeg for purposes of cleaning and testing, and within two or three weeks the soft water will be flowing from all taps. The great undertaking, under way since 1914, has cost in the neighborhood of $16,000,000. The pipe is 97½ miles long, and makes seven river crossings.

EDITOR'S NOTE

The Yarnall-Waring Co., Chestnut Hill, Philadelphia, advise us that the Yarway (formerly the Simplex) blow-off valve is of similar design to the blow-off valve suggested by K. Walsh on page 108 of POWER HOUSE for April 5, and embodies his valuable suggestion.

OUR QUESTION BOX

Questions are invited from readers regarding power plant operation and difficulties encountered

Questions Before The House

If a tube in your boiler developed a slight leak, as through a pitting that had gone through the tube, or a small sand hole, how would you stop the leak without dropping the pressure?

You have a compound engine, 11x19x 12 in. stroke, running at 260 revolutions per minute. Cut off in the high pressure cylinder is a ⅝ of the stroke. Cut off in low at 3-4 of the stroke. What is the horse power aproximately?

In the case of the above engine, what is the probable steam consumption per hour, and what size would you have to make a pump to supply the water consumed to the boiler?

10. Why is a horizontal engine, running over, provided with guides top and bottom? Which guide does the pressure act on, and why?

11. A cylinder 24 in. bore, carrying an initial pressure of 100 pounds per square inch. Allowing 5,000 pounds per sq. inch on the studs, how many would be required, and what pitch should they be set at?

12. The stays in a horizontal tubular boiler have an allowance of 6,000 pounds per sq. inch. If the segment is 24 in. high and the boiler 72 inches diameter, what is the number and diameter of stays required?

Questions Asked In Last Issue

1. A horizontal return tubular boiler, 72 in. dia. by 18 feet long, made in three courses, has sustained damage by the plate over the fire becoming overheated. The plate has come down in a blister of elliptical form, the axes being 14 in. in a longitudinal direction and 36 in. in a circumferential.

How would you put a single riveted patch on this boiler so as to preserve the full strength of the longitudinal seam? Would you put the patch inside or outside the plate?

2. In the case of a pump having a lift of over twenty-six feet, would the fitting of a foot valve be of any help in starting the pump. Generally speaking, where does the advantage of a foot valve in a suction line lie?

3. Can you state, clearly and definitely, why a longitudinal seam of a boiler requires stronger riveting than the circumferential? Show by figures the relation between the two.

4. The area of a safety valve on a boiler is proportionate to the grate area. What is this proportion, and in what way does the grate area affect the safety valve area?

5. What is the proportionate weight of air to weight of coal used to obtain combustion? Give any formula you know.

6. Can you give a clear description of what takes place when a boiler explodes through failure of a plate. What is the sequence of events?

Answers to Questions In Last Issue

1.—It looks as if it would be impossible to put a patch on this blister which would be of any great value and still retain the full strength of the seam. In order to put on a patch over the seam that would be effective, a portion of either the inside or outside lap would need to be removed, and, after the bulge or blister had been put back, the patch would be made to fit down snugly over the whole damaged part and riveted as required, the seam to fit down snugly to the patch. This, of course, would affect the strength of the seam. To put a patch over the seam straps would be more ineffective than the former course.

2.—A good close seating foot valve would, no doubt, be of great value in starting a pump with a high suction lift of 25 ft. With the foot valve on, it holds the water up to the pump all the time, and when the pump is started it just begins where it left off, without having to displace all the air in the 26-ft. of pipe to form a vacuum. (26 ft. is some lift to depend upon to supply a boiler. Why not use a deep well pump and be safer?)

3.—The force tending to rupture a boiler along the line of the longitudinal seam is proportional to the diameter divided by two, while the stress tending to pull it apart endways is only half that or proportional to the diameter divided by four. Although the pressure is exerted on both heads, only the area of one can be considered as the stresses are exerted against each other and the stress of each head, not of both, is exerted against the girth seams.

4.—Boilermakers allow ½ sq. in. area of safety valve opening to one sq. ft. of grate surface. It has been proven to the satisfaction of engineers that this proportionate area is required to relieve the boiler of the steam that one sq. ft. of grate surface can generate.

5.—Approximately 12 lbs. of air are required to burn one pound of coal, but this will vary according to the quality of coal.

6.—I have never had any personal experience with a boiler explosion, nor am I anxious to, but my idea is, that when the plate goes in a boiler, carrying the pressure boilers are subjected to, the velocity of the steam leaving the boiler so suddenly causes such a recoil (much on the principle of the reaction turbine, only a great many times more powerful) that the boiler is usually thrown from its arches, sometimes a considerable distance.—C. T. M., Chatham.

* * *

1.—It is sometimes possible to heat a blister and drive it back into place again. This, of course, is only possible when the blister is only down slightly, say, a couple of inches or so.

2.—The foot valve in the suction line of a pump is of use not only to retain the water in the line, but also prevents any material getting into the valves of the pump.

4.—The weight of air required to burn one pound of coal varies with the coal, but about 14 lbs. of air is required to give sufficient oxygen for combustion. —JOHN QUINLAN, Toronto.

* * *

6.—According to Rankin's experiments, a cubic foot of water, under pressure of steam at 50 lbs. by the gauge and at the same temperature, contains as much explosive energy as 1 lb. of gunpowder.

When a boiler bursts, especially if the rent be under the water level, the violent disturbance of the water is like putting a lighted match to the gunpowder.

This is why, when a boiler bursts, the water, instead of rushing out at the hole, explodes with such terrific force as to shatter the boiler in pieces and spreads death and devastation around.

1 lb. of gunpowder gives out an explosive force of 245.5 foot tons.—G. ALDRIDGE.

Association and Personal

Programme of C.A.S.E. Convention at Brantford

Canadian Association of Stationary Engineers' Convention and Exhibition of Power Plant Equipment and Supplies, Convention Hall, Brant Ave., Brantford, June 24, 25 and 26, 1919

THE following programme is that issued by the C.A.S.E. for their annual convention which will be held in Brantford, June 24, 25 and 26. It will be seen that the three days' convention offers features of great interest and value to every engineer who is able to be present.

Monday, June 23—(all day)—

Installing exhibits.

Tuesday, June 24

Tuesday morning:

10.00—Official opening.

Welcome to Brantford by Mayor Morrison McBride.

W. Welsh, president Brantford Lodge.

Response—W. W. Cook, Belleville.

President C.A.S.E.

C. N. Schrag, Toronto, president Exhibitors' Association.

Lieut. L. Archibald, Toronto.

Jack Armour, New York.

11.30—Meeting C.A.S.E. Executive for appointment of committees.

Tuesday afternoon:

2.00—Meeting C.A.S.E. Executive.

2.30—Ladies' trip through Brantford factories as guests of Brantford Lodge.

Tuesday evening:

8.00—Educational Session and Smoker (men only). All engineers are invited.

Lecture on Causes of Boiler Failures, by D. M. Medcalf.

Address—Fred. W. Raven, Secretary N.A.S.E., Chicago.

Lecture with lantern slides, by J. M. Brown, Hamilton, on Turbines; and C. J. Porter, Hamilton, on Generators.

Lectures on Power Plant Accessories, by S. Balmfirth.

Address—Jack Armour, New York.

Chalk Talk on Piston Valve Setting, by Secretary Drummond, of Alberta Lodge. (Pipes and tobacco will be furnished by the Brantford Lodge).

8.00—Theatre party for the ladies (Guests of the Brantford Lodge).

Wednesday, June 25

Wednesday Morning:

9.00—C.A.S.E. Executive session in Convention Hall.

Exhibition Hall open morning and evening (not afternoon).

2.30—The engineers and their friends will be the guests of the Exhibitors' Association at Mohawk Park. Special cars will be provided to take the party to the park. Ice cream and peanuts will be supplied. There will be an excellent programme of sport with valuable prizes supplied by the Exhibitors' Association.

5.45—Cars leave the park for the city.

Wednesday evening:

8.00—Meeting in Convention Hall, open to engineers and friends.

Presentation of prizes.

Prize-drawing contests.

Unique sale of curios in aid of a Brantford institution.

Music—Vocal and instrumental.

Speech by Jack Armour.

Address by C. Z. Wise, Education Secretary N.A.S.E., Madison.

Comic recitations, etc.

Thursday, June 26

Thursday morning:

9.00—C.A.S.E. Executive sessions.

Exhibition Hall open all day. (Not in evening).

10.30—Annual meeting Exhibitors' Association.

11.30—Exhibitors' Association entertains the Grand Lodge in Exhibition Hall, demonstrating exhibits and distributing souvenirs, etc.

Thursday afternoon:

2.00—Installation of C.A.S.E. officers in open meeting. Installation of officers of Ladies' Auxiliary.

Thursday evening:

8.00—Annual Engineers' Ball in the Masonic Hall, under the auspices of the Brantford Lodge. Tickets, $1.00. Ladies free. A caterer will serve refreshments which will be extra.

Visitors desiring to visit any of the Brantford factories are requested to report to Wm. Welsh or D. L. Webster. They will arrange parties and supply escorts.

For complete programme (ready about June 16), write G. C. Keith, 435 Grace St., Toronto.

Should Develop Canada

AN interesting idea has come out of the West regarding the natural resources of Canada, and what might be called a national policy of development. Prof. R. D. McLaurin, of the University of Saskatchewan, was in Ottawa recently, trying to forward the idea with the Government, and the Western members, who have formed a Committee of Natural Resources, have the matter before them.

They urge the Government to undertake a constructive policy looking to the development of the natural resources of Canada, particularly oil, iron and coal. Prof. McLaurin makes a rather interesting suggestion for solving the tariff hostility of the two sections of the country and bringing the East and West together. He argues that by developing the mineral resources of the West, and thus supplying materials for creating industrial communities there, we should develop basic national industries which every Canadian, even the grain grower, should be willing to see protected if necessary. "It is a different proposition," says Prof. McLaurin, "to protect industries necessary to the peace and security of a nation, from protecting a manufacturer who imports his raw materials from foreign countries and sells merely the finished product. By the latter method, economic independence for Canada is impossible. We should produce our own raw materials for the educational and economic benefit of our people. A nominal political independence is of less value to Canadians, when we are dependent on the United States for basic materials."

Graded Certificate For Ontario

WITH the action of the Ontario Legislature in its recent session before Easter graded certificates have practically become a reality from coast to coast. Only two provinces, Prince Edward Island and New Brunswick, still adhere to the single certificate, and action in conformity with that of the Ontario Legislature may shortly be expected in New Brunswick.

The grading of certificates is the only logical method of regulating the operation of power plants, as by it alone ability and experience are given their true value, and the operation of the larger stations entrusted to those capable of their efficient management.

Graded certificates having become law, it is of importance to note their effect on the status of the stationary engineers in the Province.

One of the most interesting results anti one which will redound most to the benefit of the engineer will result from the interchangeability of Ontario certificates with those of similar classes in other provinces.

Regulations for the working out of the Act will be made from time to time by order-in-council as has been provided for in the Act itself, and while these regulations have not as yet been developed in their final form or completeness, we are able to forecast with some degree of certainty such of them as will be of importance in the bringing of the new Act into force in January, 1920. While these regulations are tentatively given in abstract elsewhere, it is well to emphasize the method by which engineers at present holding certificates will be graded under the new law. Present holders of certificates will be divided into two classes, second and third, the standing to be set by the Board, and the first class certificate being obtained only by means of examination.

It will not be necessary for engineers at present operating a plant to obtain the certificate necessary for its operation under the new law, so long as he continues to remain in his present position, but if he changes to a plant having a higher rating the Act will necessitate his having the proper certificate for its operation, time being given for his preparation for examination.

The four grades of certificates which will be issued will permit of the operation of plants having certain boiler horsepower ratings by the holders of corresponding certificates. The exact rating for each grade of certificate is one of the regulations which will have to be determined by order-in-council, and until this is done no definite information will be available. The rating will, however, be fixed in terms of boiler horsepower, as stated in the Act, and engine or turbine capacity will not be of any moment in the operation of the Act.

It should also be noted that the Act does not come into force until the first of January, 1920. This intervening time will afford stationary engineers ample time for acquainting themselves with its workings, and if he so wishes, for preparing himself to derive the fullest benefits from its operation.

Graded Certificates for Ontario Engineers

The Passing of an Act by the Ontario Legislature Brings Graded Certificates into Operation in Ontario Starting January, 1920. The Act, with Explanations of its Various Sections and a Forecast of Regulations Which will be Made for its Operation, are Given

ONE of the bills which was given its third reading by the Ontario Legislature, on Thursday, April 17, was "An Act to Consolidate and Amend the Acts Respecting Stationary and Hoisting Engineers." This Act brings into effect the grading of certificates for engineers in Ontario and brings this province into line with other Canadian provinces with the exception of New Brunswick and Prince Edward Island, and while the Act in itself does not define many regulations which will be necessary for the examining and grading of engineers it makes provision for their carrying out by means of order-in-council. It is expected that the rating of certificates and the examinations held under the Act will be of such a nature as to conform to those in other provinces, and in this manner make the certificates issued by the various provinces interchangeable.

As before, the Act will be administered by the Stationary Engineers' Board under Dr. Riddell, Superintendent of Trades and Labor. The Act, together with such explanatory matter as is necessary to its various clauses, follows. In this Act,

(a) B.H.P. shall mean boiler horsepower or the equivalent to the evaporation of 34 lbs. of water per hour from and at 212°—15 sq. ft. of heating surface for return tubular boilers—12 sq. ft. heating surface for locomotive type boilers —10 sq. ft. heating surface for water tube boilers;

This clause defines what is meant by boiler horse power in so far as the Act is concerned.

(b) "Board" shall mean the Board of Examiners appointed as hereinafter provided;;

See Section 4.

(c) "Hoisting plant" shall mean and include a steam boiler and steam engine and every part thereof, working at a pressure of twenty pounds or over irrespective of horsepower and used for hoisting in structural operations or excavating purposes;

This clause defines what is meant by a hoisting plant and includes practically all steam hoists with the exception of those in use at mines or quarries, which latter are exempted by Clause (3) below.

(d) "Minister" shall mean member of the Executive Council charged by the Lieutenant-Governor-in-Council with the administration of this Act;

(e) "Steam plant" shall mean and include a steam boiler, a boiler and a steam engine and every part thereof and thing connected therewith or used with reference to any such boiler or engine or under the care of an engineer. R.S.O. 1914, c. 170.

(3) Nothing in this Act shall apply to the operation of any steam plant having a capacity of less than 50 horsepower, nor to steam heating plants operating at a pressure of twenty pounds or under, nor to the operation of a locomotive engine or a steamboat or a steamship engine or a hoist at a mine or quarry, nor to boilers used for agricultural purposes. R.S.O. 1914, c. 170.

Clause (3) above defines the exemptions to which the Act does not apply and to which of course graded certificates are not applicable. Power plants having a capacity of less than 50 boiler horse power (determined as in subsection (a)) are exempt. Heating plants operating at twenty pounds or under are exempt. Locomotives and steamships are also exempted and boilers for agricultural purposes; threshing engines, etc., also do not come under the provisions of the Act. It should be noted, however, that only those hoists which are used at mines or quarries are exempted, all other hoists being subject to the operation of the Act. This clause is re-enacted from the former Act.

(4) The Lieutenant-Governor in Council may appoint a Board of Examiners consisting of three competent and independent engineers practically conversant with the construction of boilers and the operation of steam plants, who shall hold office during pleasure and who, subject to the regulations mentioned in the next following section shall prescribe the subjects in which candidates for certificates of qualification as stationery or hoisting engineers shall be examined and shall conduct or provide for and supervise the examination of candidates and report thereon to the Minister. R.S.O. 1914, c. 170.

Clause 4 above is the same as that in the former Act and provides for the setting up of the board by which the examinations are conducted. In itself it effects no changes but in the provisions for setting up regulations which follow important changes have been made which apply to the grading of engineers and to the carrying out of the law.

(5) The Lieutenant-Governor in Council upon the recommendation of the Minister may make regulations for:

(a) The examination of candidates, the granting of certificates, the classifying of these certificates into their respective grades, and the evidence to be furnished by candidates as to previous training or experience and sobriety and good character; and the recording of changes made in engineer's positions;

This section makes provision for the grading of certificates and also for the recording of changes which may be made from time to time in the positions held by engineers.

(b) Determining the time of duration of certificates and their renewal;

(c) Fixing the fees to be paid by candidates upon examination and for certificates and their renewal;

(d) Prescribing the causes for which a certificate may be revoked, cancelled or suspended and for

(e) Fixing the fees or other remuneration to be paid to the members and officers of the board. R.S.O. 1914, c. 170.

(f) Fixing the fees to be paid by plant owners for certificates of registration.

(6) No person shall be elegible for examination unless he is a British subject, or has resided in Canada for at least one year. R.S.O. 1914, c. 170.

7—(1) On the recommendation of the board and on payment of the prescribed fees, the Minister may issue certificates of qualifications to stationary or hoisting engineers, and certificates of registration to plant owners.

(2) Subject to the regulations a certificate may be revoked, cancelled or suspended by the Minister on the recommendation of the board at any time.

(3) Every stationary or hoisting engineer shall, during the continuance of his certificate, register with the board on or before the 1st day of February of each year on a form to be furnished by the board, and any stationary or hoisting engineer who fails to do so shall not continue in charge of a steam plant unless by special permission of the board. R.S.O. 1914, c. 170.

(4) It shall be the duty of all owners of steam plants to advise the board, on a printed form supplied by the board on application, of the B.H.P. and steam pressure of their plants, on receipt of which, together with the prescribed fee, the Minister will issue a registration certificate. Any change made in the plant subsequent to registration will necessitate a re-registration of same.

(5) It shall be the duty of all engineers and firemen who come under this Act to report annually to this board on a form which will be supplied, the B.H.P. and steam pressure of the plant which he is operating.

8. A person who is not the holder of a certificate shall not operate or have charge of any steam or hoisting plant

except in case of emergency, when he may be employed in operating any steam plant for a period not exceeding thirty days at any one time. R.S.O. 1914, c. 170.

9. The board at its discretion may grant a provisional certificate to be good for a period not to exceed one year to any person who holds a stationary or hoisting engineers' certificate from the board of examiners or other duly constituted authority of any other Province of Canada. R.S.O. 1914, c. 170.

10. The certificate shall at all times be exposed to view in the engine or boiler-room in which the holder thereof is employed. The registration certificate to be exposed to view in the engine or boiler-room also. Failure to keep such certificate exposed shall be *prima facie* evidence of the lack of qualification under this Act. R.S.O. 1914, c. 170.

11. This Act shall not apply to firemen, who have had less than six months' experience, or other workmen acting under the personal direction or supervision of any engineer holding a certificate under this Act, who is actually in charge of a steam plant, or to the employees of engine builders or steam plant contractors engaged in installing, setting up or testing a boiler or steam plant. This section shall not apply to hoisting engineers. R.S.O. 1914, c. 170.

12. Any person who deems himself aggrieved by the decision of the board may appeal therefrom to the Minister, upon giving such notice as the Minister may prescribe and the decision of the Minister shall be final. R.S.O. 1914, c. 170.

13. The board shall on or before the 15th day of November in every year make to the Minister a report in writing for the year ending on the 31st day of October of the previous year, showing:

(a) The number of certificates granted;
(2) The number of applications for certificates refused and the causes for refusal;
(c) The number of certificates revoked, cancelled or suspended, and the causes for the same;
(d) The amount of fees received from candidates or holders of certificates;
(e) The number of boilers registered during the year;
(f) The amount of fees received from plant owners for registration purposes;
(g) Such other matters as may be directed by the Minister or the Lieutenant-Governor in Council. R.S.O. 1914, c. 170.

14—(a) Any member of the board, or inspector, on presentation of authority in writing, signed by the Minister, may enter any premises wherein he has reason to believe there is a steam or hoisting plant and make such inspection as may be necessary to determine whether the provisions of the Act are being complied with.

(b) Any person who interferes with or obstructs a member of the board in the exercise of the powers conferred on him, shall incur a penalty not exceeding $100.

15. Every person who
(a) Except as provided in section 8, operates a steam or hoisting plant as the engineer in charge thereof without the certificate required by this Act, or employs or permits any person to operate a steam or hoisting plant as the engineer in charge without such certificate; or
(b) Is guilty of a contravention of subsection 4 of section 7, shall incur a penalty of not less than $10, nor more than $25. R.S.O. 1914, c. 170.

16. It shall be the duty of the inspectors of factories to assist in the enforcement of this Act, to report to the board any violation thereof, and to furnish to the board such information as they may have as to the conduct and capability of any person holding or applying for a certificate. R.S.O. 1914, c. 170.

17. The penalties provided by this Act shall be recoverable under *The Ontario Summary Convictions Act.*

18. *The Stationary and Hoisting Engineers' Act* being chapter 170 of the Revised Statutes of Ontario, 1914; the Act passed in the 4th year of His Majesty's reign, chaptered 28; and section 17 of *The Statute Law Amendment Act,* 1915, are repealed.

19. This Act shall come into force on the 1st day of January, 1920.

Explanatory

Subsection (d) above is to be read in connection with Clause 7, Section 4 below, and applies to the registration of power plants by their owners.

It will be seen that this Act sets up the machinery for the grading of certificates, the registering of plants which come under the Act and the making of regulations for the carrying out of the Act.

It is probable that four classes of certificates will be issued: first, second, third and fourth. The fourth class certificate will embrace all firemen having six months' experience, night watchmen and water tenders. The holders of this grade of certificate will be required to know how to operate a boiler in a safe manner.

The third class certificate will be the lowest engineer's certificate and will be required of those operating steam plants of 50 boiler horse power or over, up to the lower limit of the next higher class.

The second class certificate will be required of those having the operation of plants of greater capacity in their care.

The first class certificate will be the highest grade and will be obtained only by examination. This examination will necessarily be of a highly technical and practical nature.

Present Holders of Certificates

Engineers who hold certificates at present will be divided into two classes: third class and second class, the standing to be set by the Board. New applicants, those holding no certificate, and those wishing to obtain a higher standing will have to pass the examinations for the class of certificate wished. Application forms will be sent to all engineers holding the present certificate, on which they will set out their standing, and this standing will determine their grading into the two grades above mentioned, second and third.

A most important question which many engineers will probably be interested in is the effect that the new Act will have on their present positions. That is to say, an engineer who will be given a third class certificate may at present be in charge of a plant which under the new law will require a second or first class certificate. His position will not be affected in the least. So long as he remains in operation of the same plant he will not be interfered with in any particular so far as his grading is concerned, but if he changes his position and goes to another plant where a higher class of certificate is required then he will be required to pass the examination for the particular class in question. This might in some cases work hardship and so time will be given for him to prepare himself for the examination.

Examinations

The examination for the fourth class certificate will be entirely oral and the questions asked will be those which will give an indication as to the candidate's understanding of boiler operation, particularly safe operation. The examination for other grades will be written examinations.

Any one who desires to try any of these examinations on and after the first of January, 1920, may do so by making application to the Board for an application form, which will be furnished. The first week of each month will be set for examinations in the Board offices, commencing on the first Monday in the month. Examinations will also be held at local points as at present, such as London, Kingston, Ottawa, Port Arthur, and elsewhere. Examinations will be conducted by the Board of Examiners and such other assistants as they require.

Registration of Plants

In the furtherance of this legislation all power plants coming under the Act will be registered and the boiler horse power of all plants in the province will be obtained. Registration certificates will be issued and these certificates will be permanent unless alterations are made, in which case a re-registration will be necessary.

Change of Positions

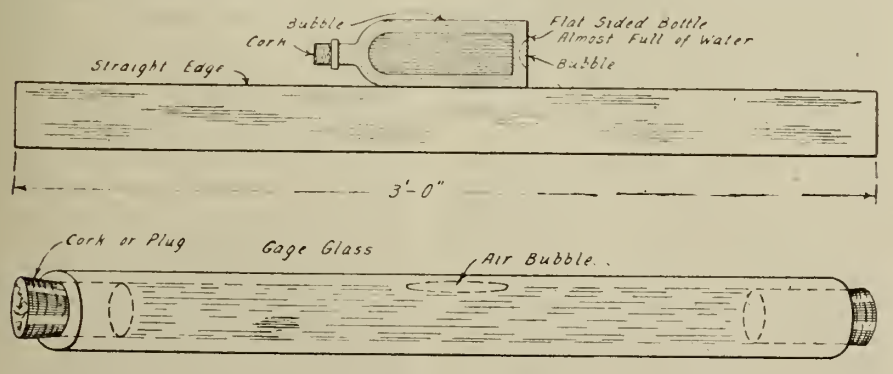
Any engineer making a change in position after 1919 will be required to notify the Board of such change.

The Operators' Point of View

LEVEL MADE FROM GAUGE GLASS

L. C. Bond

WHEN out on a job and a level is needed for lining up work, one can be improvised by filling bottle with water and laying it on a straight-edge. However, a bottle with parallel sides cannot always be obtained readily. A more satisfactory level can be made by following the suggestion of Fig. 2. The scheme of using a bottle for a level is shown in Fig. 1. To make the level of Fig. 2 a piece of water-gauge glass is used because these gauge glasses are usually true. Fill the gauge glass full of water and then insert a cork or a plug in the holes in each end. Of course, the gauge glass, when in use, is usually held on one face of a straight-edge. It is often desirable to attach the gauge-glass level permanently to a straight-edge with a couple of pieces of tin, one at each end, bent over it in the form of straps. It should be noted that the glass tubes in the levels which are regularly manufactured are curved somewhat so that when the straight-edge is level the bubble will lie in the centre of the tube. However, the gauge glass of the improvised level is not curved, but is straight. Therefore, when using one of these tubes it may be level when the bubble is just free from the plug in one end or other. It is not necessary that the bubble be in exactly the middle of the tube. It is a good plan, when using a level of this sort, to turn the gauge glass end for end to be sure that the bubble does not touch the plug in either position.



IMPROVISED LEVELS.

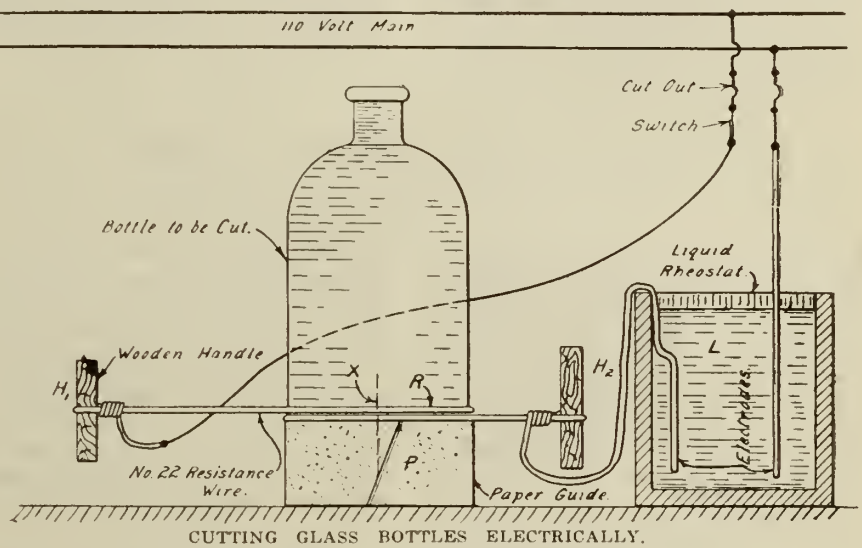
CUTTING GLASS ELECTRICALLY

H. M. Holt

(Copyright. All rights reserved.)

We have cut bottles with an electrically heated wire (Fig. 1) and have found this method more successful for cutting off bottles than any other one that we have tried. The first step where a bottle is to be cut, is to make a file mark at the location where the glass is to be cut off. The function of this file mark is to start the crack around the bottle in the right direction. Then a strip of paper, P, is wrapped around the bottle, just below the file mark. This strip acts as a guide by indicating just where the wire, which will be heated electrically, should be wrapped around the bottle. Then encircle the bottle with a length of high resistance wire, R. Small iron wire will do but probably No. 22, B. & S. gauge Nichrome wire will be found as satisfactory as any. Where the wires pass each other (at point marked X in the illustration) they may be prevented from contacting by the insertion of a piece of sheet asbestos or may be held apart simply by providing sufficient tension on the handles H1 and H2.

The source of voltage may be an ordinary 110-volt incandescent lighting circuit. To limit the current to the proper intensity, some sort of a rheostat should be provided in series with the arrangement. A simple liquid rheostat, L, is usually most convenient. Salt water can be used in the glass vessel, L, and the electrodes may be dipped into it to a sufficient distance that the current through the resistance wire, R, is of the right intensity to raise the wire to a red-heat temperature. About 10 or 12 amperes is usually required. The wire being red-hot, the operator pulls gently on the handles H and H. After the current has been flowing for about half a minute a cracking sound will usually be heard. This indicates that the bottle has cracked under the wire. In some instances it may be necessary to tap the bottle with a light tool after the heated wire has been applied in order to start the crack.



CUTTING GLASS BOTTLES ELECTRICALLY.

Circles and irregular shapes may be cut from sheets of glass, using the general methods described above, by holding the hot resistance wire on the glass plate in the contour to which it is desired to cut the sheet.

DIRECT OR ALTERNATING CURRENT MOTORS FOR CRANES

M. O. Huntington

(Copyright. All rights reserved.)

If both alternating and direct current are available in a plant it is probable

that direct-current motors are preferable to alternating current for crane service, particularly where time in handling must be minimized. Direct-current series motors are used for crane service. With these as the load decreases, the speed of the motor increases, so that with these motors light loads may be handled rapidly.

However, alternating-current motors will, from an operating standpoint, give entire satisfaction for crane work. At this time practically all of the alternating-current motors used on cranes are three-phase machines, but it is not improbable that in the future single-phase motors having approximately the same load speed characteristics as direct-current series motors will be used widely. The 3-phase alternating-current motor is best adapted for crane service applications where maximum speed of handling is not an important factor. In general, alternating-current motors will cost more than the equivalent direct-current motor for crane service.

To summarize the advantages of the direct-current motors for crane service are: (1) High no-load speed for return of crane hook because of series characteristics; (2) Simplicity of control apparatus and wiring; (3) Minimum amount of space required for motors and control apparatus. The advantages of the three-phase alternating-current motors for crane service are: (1) Expense of installation of a motor-generator set may be eliminated where only direct current is available; (2) More rugged and simpler construction which insures a minimum maintenance expense; (3) Satisfactory operation under adverse conditions, such as where motor is exposed to cement, dust, ashes, coal or an excess of any kind of dirt.

The last-mentioned advantage of alternating-current crane motors has dictated their installation in a number of applications in cement mill, steam plant and similar service.

YOUR FIRST JOB AS CHIEF

By J. M.

YOU have just been appointed to a job, the job you have been planning, scheming and studying for, for a considerable time past. It is not a big undertaking, just a plant that a third-class certificate will cover, but you are chief engineer, and instead of having to receive and execute orders you will now have to depend on your own ability and resources to keep your plant in running order.

On taking charge your mode of procedure will depend very much on circumstances, whether the plant is running, or whether it is shut down for overhaul or any other reason. In any case, whether running or shut, one of your first duties will be to notify the Government boiler inspector that you are now in full control of the boiler and engine of such and such a pant. The boiler certificate should also claim your attention and if it is still in force well and good, but if it has expired no time should be lost in informing the boiler inspector of the fact. Further, your employer should be told immediately that the inspection of the boiler is overdue, and that arrangements must be made for a visit of the boiler inspector at the earliest possible date.

On taking charge you find that the plant is running and there is no opportunity for you to examine either boiler or engine, other than giving a cursory glance as to the general lay-out. Fortunately, the night engineer has been on the job for some time and the first morning you arrive to start up, you find he has steam up and the engine warmed through ready for operation.

Five p.m. finds you tired, very tired, after a day of considerable moving around on your part, as many things have happened to cause you worry, and mostly all because you were strange to the job, and perhaps a trifle too anxious to make good. The fuel was very poor, consequently the steam pressure was kept very unsteady, and that fireman was certainly running with the water low in the glass at times, the injector or feed pump was not always to be depended on, you could feel the blow-down pipe distinctly warm, proving a leaky blow-down valve or cock or both, and there were quite a number of glands and joints fizzing away valuable steam all day long. That engine seemed to be running queer, not at all like the last one you were looking after, for apparently no reason a black streak would appear on the bright piston rod, a bearing would feel suspiciously warm, the slide valve started to chatter, but you got through the day without having a shut-down.

Tired as you felt there were so many little things you would like to do after shutting down, but the plant is running overtime, and you had to leave things as they were to the night engineer. You went home hoping for a better time the following day and the days to come, and you did have a much pleasanter time, petty things that previously worried you scarcely ruffle you now.

The persuasive arguments, rush orders, etc., of your employer have prevailed with the boiler inspector to allow you to run the boiler for another week or two or perhaps for a further month or two, and you want to have a look at that boiler badly. There surely must be lots of scale on the tubes, of this you are quite convinced. The other day during the noon hour when you had a look at the combustion chamber and tubes they looked dirty enough to require a good brushing out, and there were quite a number of air leaks around the brickwork, all helping to interfere with good combustion. But the dirty tubes and combustion chamber, and the air leaks did not seem to you to account for the poor steaming qualities of the boiler, even allowing for the inferior quality of the fuel, so you decide that scale is at the root of the trouble. To have that scale removed might mean the sacrifice of a Sunday's leisure, but rather than continue to operate with a hard steaming boiler you determine to have the job done, and the way that boiler steamed the following week repaid you for all your extra labor, and by the way, your reputation as an engineer who knows his job will have been considerably enhanced, not only in the opinion of your employer, but you will have raised the status of the engineer among your fellow workmen.

Supposing you take over the job when it is shut down.

Fortunately there will be plenty of time to overhaul both engine and boiler, and the boiler will claim your attention first.

After a thorough examination both internally and externally, you will get your men to work chipping, scraping and cleaning wherever necessary, repairing the furnace bridge wall and grate bars, and stopping up any cracks in the brickwork setting. Maybe a few of the tubes will be all the better for an application of the tube expander, and there are leaks in the boiler seams that require caulking, in fact the hundred and one jobs around a boiler that need your attention will be done. Having previously arranged for a visit of the boiler inspector you have made sure everything is in readiness for his arrival. Boiler clean inside and out, safety valve dismantled and the flange blanked off, provision made for filling the boiler in the quickest possible time, a connection ready for attaching the test pump, and don't forget to have a portable light ready. It may be a candle, electric or acetylene lamp, but have it ready, as all inspectors don't carry their own light. If you have had the time and the necessary test pump or natural water pressure you will likely have put a working pressure test on the boiler for your own satisfaction and lucky you did too, for a leak that had escaped your examination showed up pretty bad when the water pressure was applied. Inspectors vary in their methods as to inspecting and testing a boiler. Some of them want the water test applied first, while others prefer to examine the inside first and then apply the test. This making ready for an inspection has meant quite a lot of work to you, but you find the inspector a real nice fellow, he seems well pleased with your efforts to have everything in good order, and suggests several improvements here and there that you yourself had thought of, but being new to the job you did not care about speaking of them to the boss. However, armed with the authority of the Government inspector you suggest that these alterations be made, and they are made.

While your men have been busy cleaning the boiler you had found time to have a look at the engine, and tak-

ing it all together you found it in fairly good shape. The cylinder walls were smooth and true, the piston rings were a good fit, the slide valve was scored a little but nothing more than you could take down with a scraper. You found a good grade of packing in the piston rod and valve spindle glands and decided to leave it alone. The babbitt in the crank pin and crank shaft bearings you considered was of a good quality and a slight adjustment was all that was required.

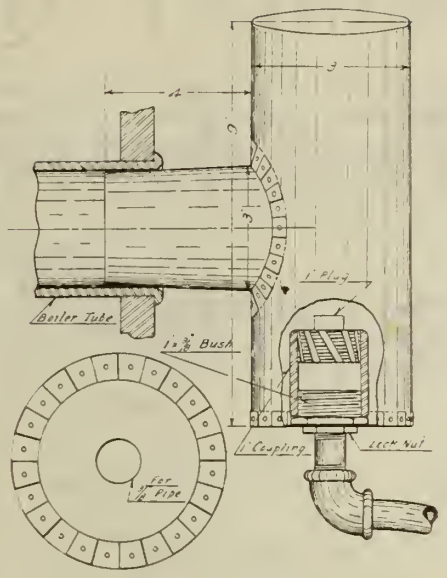
Thoroughly satisfied with your examination and overhauling you report to headquarters that you are ready to start up at any time.

Your success or failure in your new job will depend as much, if not a great deal more, on your personality as on your ability to fulfil the duties of an engineer-in-charge. Your predecessor may have been a man who by his ability and strength of character made the position of the engineer one to be respected and looked up to, and by following in his footsteps both morally and practically your success will be assured. On the other hand you may be taking the place of a so-called engineer, who by his lack of ability has brought into derision the position of the engineer, one who has lost the respect both of his employer and his fellow employees. His shortcomings as an engineer were not even compensated for by a stock of good manners. By his overbearing and swaggering behaviour he had antagonized everybody around the plant, and in this latter case your position may be somewhat difficult for some little time. However, by strict attention to your duty, courteous behaviour to all who come in contact with you, and firmness in maintaining your position when necessary, your job will in time be worth as much and more to you then you ever anticipated. "Be friendly and you will make friends." The consciousness of a duty faithfully performed will bring its own reward, and the experience gained from your first job as chief should be a stepping stone to one of the big jobs you have viewed from afar off.

A "CLEAN" TUBE CLEANER

By E. N. Howard

The accompanying sketch illustrates a simple device that is doing efficient service at the plant where the writer is employed. When blowing out tubes with steam or compressed air, the boiler room generally assumes an aspect of inky blackness, which eventually settles upon everything in sight. To overcome this trouble, and make the place more livable, it was found necessary to devise some means to eliminate this objectionable feature. The appliance here shown was originally made from 2-inch pipe fittings, but the sensation of holding this at the end of a pipe about 6 feet long proved tiring, to say the least. In looking round for something lighter the writer came upon some 3-inch conductor pipe which had been discarded when the roof was being fixed. When this was cut and put together as per sketch, it was found to be even more reliable than that previously used. The entire apparatus cost less than a dollar and the efficiency may be judged from the fact that in the past three years this has been used the tubes have only been cleaned with a rod about half a dozen times. This method has also an advantage over blowing the tubes inasmuch as there is no tendency to catch the soot on fire and blow back through the fire doors. It is also much cleaner as the soot goes up the stack instead of (as in a great many cases) into the boiler room.



A CLEAN TUBE CLEANER.

THE STATUS OF THE ENGINEER

Editor the POWER HOUSE:

Why is it that the pubic do not know that stationary engineers are among the most progressive people in the world so far as preventing waste in their own particular line is concerned, namely, fuel, oil, labor, machinery, etc. The answer is easy. They do not use the newspapers enough, they do not advertise. Practically every engineer who is a member of some engineering society, club, or association understands and knows what engineers are doing. Every engineer who is a reader of a power plant magazine knows the same thing, only more so, as any good journal will teach a faithful reader more about his work than he can learn at a meeting once or twice a month. However, both are good in their own place, but outside of the above class of folks there are very few who ever give the engineer a single thought. In the good old days when there were more fatal accidents around power plants, usually causing the death of the man called the engineer, the public did know that such folks did live or die. But in our day the engineer is usually so free from blame when an accident does occur that the name seldom shows in any important part of the report. This is very good. So far as the engineers are concerned, it shows they are a safe financial investment. The employers of engineers have probably noted these changed conditions and the money end of the deal is the only one interesting them. Why, it is not unknown, for some manufacturers to work "tooth and nail" to prevent the passing of a license law for engineers, the idea being that he would have to part with a few dollars more if such a law was in force. If engineers could collect a fund to be used for the paying for space in the newspapers, to educate the public to the important position in the world held by the stationary engineer, it would be money well spent. This world war has been a war of science and engineers—we have seen something like this over and over again in the newspapers. Has the stationary engineer been in the mind of the public at any time when reading the above sentence? Every other kind of an engineer, but not the stationary power plant man. No doubt there were thousands of cases where remaining at his post was necessary during bombardments of the power stations, and it is just as certain that he remained on duty until the plant was wrecked and himself killed, but the dear public never noticed anything about it in print. The stationary engineer, like other scientists who have become famous in spite of themselves, are as a rule very modest. So much of their time is used up studying how to reduce cost of operation, etc., that they are apt to neglect their own financial interest. To be one of the best is a fine thing and well worth a struggle, but if you have a little change to spare after looking after the welfare of the wife and kiddies there are good books to buy and experiments to make. Neither books nor experiments will materialize to any great extent, unless the employer loosens up somewhat more than usual in the great majority of plants. Therefore get the newspapers to tell the people who you are and what you are doing. When they begin to notice that there are such animals on the earth's surface, even if under sky-reaching piles of brick, stone and cement, and realize that practically the comfort, safety, and conveniences of a city largely depend on the careful work of the engineer, then and then only will the power plant engineer begin to come into his own. The better class of power plant journals are forever fighting for the interest of the engineers, well and good, but about the only readers such journals have are the engineers themselves and the advertiser and the advertisers' managers. In the two latter cases it is safe to predict that many of them study mighty little in the journal outside the selling section. What the engineers require to do is to get before the public eye, and in the public mind, as they really are in the plant. Here is a chance for original sane suggestions.

James E. Noble, Portsmouth, Ont.

Combine nearly every pumping requirement

Fairbanks-Morse Pumps are the kind that produce results; the kind that give the maximum pumping economy.

Suitable materials, high-grade workmanship, and proper engineering application are the prime reasons why these pumps will best suit your needs. Nearly every pumping installation requires more or less of the items listed at the left.

Send us your complete specification and let us quote on your complete outfit.

BOOK REVIEWS

The Fundamental Equations of Dynamics, by Frederick Slate, University of California Press, Berkeley, Cal. Price, $2.00.

The established connections of dynamical reasoning with other fields in physics are of increasing number and closeness, and a need has arisen for a treatment of the subject which would coordinate the more fundamental concepts of dynamical theory without encroaching on the more specialized fields which would demand more than one volume for their comprehensive treatment. The present work deals with the principles which lay out and direct all the main lines of thought.

An introduction summary develops a general conception of dynamics and leads to the treatment of the six fundamental equations which follow in the second chapter. The third chapter deals with reference frames, transfer and invariant shift, while the fourth takes up the main co-ordinate systems. The fifth is devoted to explanatory notes on the preceding ones, and discusses various phases of the development of dynamical theory. For those possessing a sound knowledge of higher mathematics and to whom dynamics is a study of absorbing interest the work is commended.

Schweitzer & Conrad Inc., 4431 Ravenswood Ave., Chicago, have issued a new catalog descriptive of their voltage protective and switching equipment. This publication describes and illustrates the various types of fuses, liquid pattern, made by this firm, and also describes the various methods by means of which fuses are incorporated in the design of various types of apparatus, to the greater protection from the results of emergency conditions. In addition to the fuses the publication describes safety disconnecting switches, high voltage circuit breakers, ejector primary cutouts, etc.

Philadelphia.—The Electric Furnace Construction Company, Finance Building, Philadelphia, reports the successful starting up of a special "Greaves-Etchells" type of electric furnace for the manufacture of corundum at the works of the Wm. W. McGregor Co., Airdrie. The material used for the charge is the waste dust accumulated from the crushing of natural corundum. This was practically useless and was considered to be a waste product. A charge of 7 tons of this material was treated in approximately eight hours. The total energy consumption was 3,500 units and the usable corundum ingots weighed nearly four tons. Results of the tests made gave great satisfaction and promise a new field for the electric furnace. We understand that a fairly constant load was obtained throughout the whole of the operation.

SALE OF
SURPLUS MILITARY AND NAVAL STORES

DRY GOODS, CAMP SUPPLIES, FOOD, HARDWARE, SCRAP METAL, JUNK

Cloth; new and second-hand clothing, equipment, hardware, tents, blankets, camp supplies, etc. :: Flour, jam, canned evaporated milk, tea, coffee, etc. :: Condemned clothing, junk, old brass, metals, leather, rubber, etc.

SALES WILL BE MADE BY SEALED TENDER

Persons desiring to tender are requested to communicate with **THE SECRETARY OF THE WAR PURCHASING COMMISSION, BOOTH BUILDING, OTTAWA,** stating the items in which they are interested, whether new or second-hand or both.

Arrangements will be made to have samples on exhibition at places throughout Canada; specifications, full details, and tender forms will be mailed when ready to those who have registered as suggested above.

IF INTERESTED PLEASE APPLY NOW

Institutions May Make Direct Purchase Without Tender

Dominion, Provincial and Municipal departments, hospitals, charitable, philanthropic, and similar institutions which are conducted for the benefit of the public and not for profit may purchase goods without tender at prices established by the War Purchasing Commission.

All communications should be addressed to the Secretary, War Purchasing Commission, Booth Building, Ottawa, who will be glad to supply lists and further details to those interested.

TRADE GOSSIP

Making Water Meters.—The Neptune Company of New York, the largest manufacturers of water meters in the world, have decided to locate a branch manufacturing plant in Canada. They will be incorporated under the name of The Neptune Meter Company, Limited, of Canada. They have obtained floor space on the corner of King and Dufferin streets, in the former munition factory of the Russell Motor Company, and will, just as soon as it is practicable, equip a factory for the manufacture of water meters for the Canadian trade. The parent company has done a very large business in Canada during the past ten years, and will now be in a position to render very prompt service in the way of supplying repair parts, etc.

Open Montreal Office.—The Canadian Link-Belt Co. have opened a branch at 1195 St. James St., Montreal. A liberal stock of popular types of Link-Belt will be carried in stock at Montreal in the future from which all orders in that section will be promptly filled. This will not only enable the Canadian Link-Belt Company to render its customers a more prompt service than has hitherto been possible, but will also effect for them a considerable saving in freight and express. For the present the Montreal branch will serve largely as a warehouse, all engineering assistance being ren-

Cable Address "Willwills" Montreal, P.Q. Established 1891

Williams & Wilson's

"Lancaster" Patent Steam Trap

For all pressures from 2 lbs. to 300 lbs. Very compact. Float is made cylindrical and extends the full length of the box, enabling a float of greater capacity than the ball float to be fitted in much smaller space.

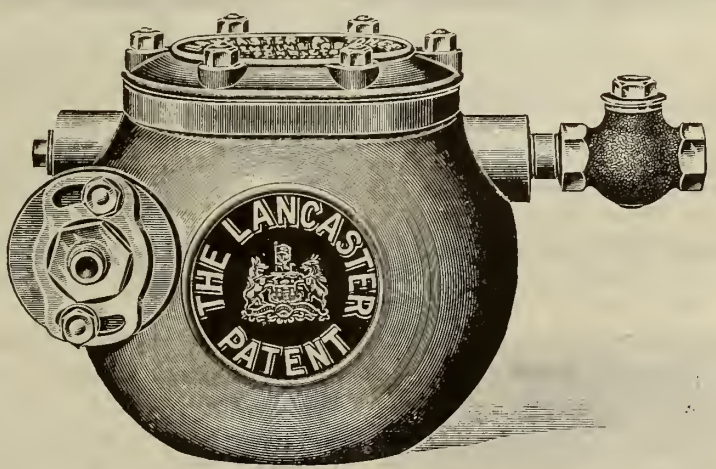
To show the compactness of the new trap, we may say that the ⅜ in. trap is 8⅜ in. high, 10½ in. long, 6½ in. wide over all. **The SPECIALTY OF "THE LANCASTER" STEAM TRAP** consists in the **Loose Disc Valve** at the orifice of the discharge pipe in connection with a **quick-threaded screw** motion, worked by the float. This valve is **frictionless** in action, and, being loose, **cannot stick** to its seat. It is very prompt in its movements for opening and closing the discharge pipe, and the working parts are **very simple and easily examined.** It also acts as a **Safety Valve,** as any excessive pressure exerted against the face of the loose disc valve would, by virtue of the Quickness of the Screw Thread, force it open.

THE "LANCASTER" STEAM TRAPS ARE RELIABLE, ECONOMICAL AND EFFICIENT.

The Lancaster Lifting and Marine Steam Traps

(R.T.M.)

These Traps are similar in construction and action to **"THE LANCASTER" STEAM TRAPS,** with the exception that being made with a much stronger box and fast lid, they will raise the discharged water **2 feet for each 1 lb. pressure of steam.** The condensed water and air pass away with the greatest ease.



These Traps Cannot Stick, and have **Never Yet Failed** under most **Severe Tests.** In ordering, please state Size and Steam Pressure.

Write for full information. First Trap sent entirely on approval.

Agents for the DOMINION OF CANADA

dered by the Canadian Link-Belt Company at Toronto, where Link-Belt is manufactured for the Canadian market. Although shipments for the Montreal and Quebec territory will be shipped from the Montreal branch all correspondence should continue to be addressed to the Canadian Link-Belt Company, Toronto.

SAYS PART OF STEAM LINE OUGHT TO BE ELECTRIFIED IN THE EAST

W. G. Gordon, transportation engineer of the Canadian General Electric, read a paper on "Main Line Electrification in Canada," with special reference to the Moncton-Halifax line of the Canadian National Railways.

"The latest heavy trunk line electrification to contribute data illustrating successful operation is the Chicago, Milwaukee and St. Paul Railroad. This line has in electric operation 440 route miles, and has let contracts for the electrification of a further 220 route miles.

Saving in Ton Mileage

On a steam operated trunk line twelve per cent. (12%) of the entire ton mileage movement of freight and passengers carried is represented in the cars and tenders required to haul the coal supply for the steam locomotive. When such a line is electrically operated from water power stations it means that the total movement for railway coal and locomotive tenders is eliminated; and, even if partially or wholly operated from steam power stations, the movement for locomotive tenders is eliminated, and the movement for railway coal is greatly decreased. The benefit is self-evident of being able to apply this ton mileage in the movement of revenue tonnage.

"The cost of maintenance of the electric locomotive is very much less than that of a steam locomotive. The steam locomotive is a power plant which, owing to physical limitations, can attain only a certain capacity and efficiency. On the other hand, the electric locomotive, itself very efficient, can draw any amount of power desired from a system fed either by hydro-electric plants or highly efficient steam electric plants.

"With regard to the 187 miles of the present steam-operated line of the Canadian National Railways, between Moncton and the Halifax Ocean Terminals, it can be shown that the electrification of this line is economically justified on the basis of sound engineering principles. In Halifax the Ocean Terminals have been laid out with a capacity of several times the present traffic, and with ultimate provision for many times the present tonnage, whereas the present line is a single track railway, with heavy grades. To increase the tonnage capacity of this line several plans may be considered, including electrification, grade reduction on the present line, double tracking the present line with grade reduction, double-tracking the present line without grade reduction and construction of low grade single track on new locations.

"During winter conditions of extreme cold the steam engine is at its worst, owing to the dissipation of heat, while the traffic conditions are most severe. This condition, instead of being detrimental to the operation of the electric locomotive, increases its service capacity as the motors can more readily dissipate heat. Further, the tonnage traffic over the line can be largely increased, due to the electric locomotives being able to haul much heavier tonnage at higher scheduled speeds with almost an entire elimination of the failures and delays at present due to steam operation.

"It is human to err," and in our last advertisement the printer let us down. He made a simple error. Not being an Engineer, of course, he couldn't see the importance of the error.

He substituted the word "STEAM" for the word "FEED," which is quite a different thing. The ad. referred to the coal consumed in "feeding" boilers by two different methods—the "Direct" Steam Pump, and the "Direct" Return Steam Trap.

The coal piles above more nearly represent the comparative amounts required to "steam" boilers when using Cole Direct Return Traps, feeding hot condensation as feed water into boilers.

Approved by Boiler Inspector, Ontario

Cole Return Traps and Automatic Boiler Feeders

will certainly make a big cut in your fuel bills. Write for our Bulletins, on "Condensation" and on "Boiler Feeding." They show how fuel economies are effected.

NEW CANADIAN INDUSTRY

The Canadian Corkboard Co., Ltd., 17 Adelaide St. East, Toronto, an entirely Canadian company dealing in cork insulation and other cork products, has recently made its first shipment of corkboard to Mohawk, Ont., and their plant is in a position to make immediate shipment of pure corkboard, impregnated corkboard, and granulated cork. This plant affords the Canadian plant owner the opportunity of purchasing Canadian-made cork products, where formerly he was forced to obtain them in the United States and Spain. The present company have taken over the plant formerly operated by the Robinson Brothers Cork Co., Ltd., at Port Colborne, Ont., and it is of interest to note that Mr. A. C. Robinson has for some time past seen service in Palestine. Mr. Frank White, who was ten years with the Robinson Company, is the sales manager, with headquarters in Toronto, and Mr. H. M. Edwards is the assistant sales manager, located also in Toronto. Mr. Edwards was formerly with the Armstrong Cork Co. for seven years, and five years with the Johns-Manville Co. The Canadian Corkboard Co. are prepared to sell materials and to furnish specifications, or to undertake the installation complete.

NEW POWER HOUSE

The Public Works Department proposes to construct a power house and laundry in connection with the Military Hospital building at Lake Edward, P.Q. It will consist of a basement and one storey, with concrete foundations. The basement will contain coal bunkers at the rear, engine, dynamo, pump rooms and workshop at the right hand side, the central portion being used for the laundry. The dynamo room is to be separated from the pump room by a 9 in. brick wall, and the laundry will be cut off from the other section by 14 in. brick walls. The first floor will contain another portion of the laundry, including the disinfection room, with stores and toilets. A high brick chimey is also to be erected, having a cast iron cap. The foundation walls and beams, including the chimney foundation, are to be

Requires Very Little Attention

Do you want efficient and reliable steam trap service without having to give the trap constant attention? Then adopt

The Long Patent Steam Trap

Has important features which CLAIM your attention. Absolutely guaranteed. The Long Trap is automatic and requires no valves except those which control the admission of steam to the apparatus to which the trap is attached.

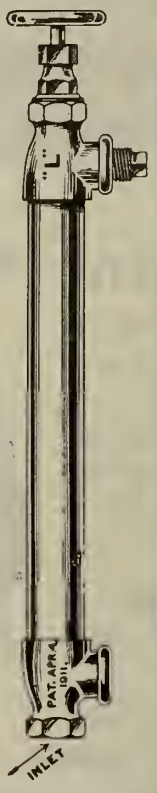
The trap is regulated to work against any pressure between 1 and 200 pounds.

Being open at starting, it cannot become air bound, this doing away with air cocks or vents—Does Not Freeze.

It is capable of draining from 900 to 1,500 feet of one inch pipe.

The Long Trap may be applied to drain steam mains, jacket kettles and separators, and can also be used in drying room systems.

Write for further explanation to



J. T. LONG
84 Adam St.
MONTREAL, CAN.

If your dealer does not sell it, write direct. No. 2

of concrete. The boilers are to be carried on girders supported by concrete piers.

The floors of the boiler room, bunker, engine and dynamo room, and pump house will be of 4 1-2 in. concrete, with a wearing surface 1 1-2 in. thick. The floor and laundry roof over the bunkers will be of reinforced concrete. The main floor is to be covered with asbestos shingles, and the roof of the other portion with tar and gravel.

The power plant will consist of a 20 k.w. 125 v.d.c. generator, multipolar type, direct connected to a steam engine. The panel board is to be of the double branch type. The system of wiring will be designed for the parallel two wire 110 v. d. c. interior conduit system.

ITALY UTILIZES VOLCANIC POWER

The present enormous price of coal in Italy, according to the Italian Bureau of Public Information, has resulted in the realization of an idea which at first thought seemed but a dream, but which instead has been developed in a marvellous manner and is assuming quite considerable importance; this is the industrial exploitation of one of the features of vulcanism and that is the natural heat emitted from the soil in those regions more or less volcanic in character.

The first experiments along this line were made some years before the war by Prince Ginori-Conti in Tuscany at Larderello, near the salt-mines of Volterra, a region extensively covered with volcanic formations, the most wonderful being the so-called "soffioni," which are certain volcanic vents emitting powerful jets of very hot steam containing boric salts and various gases used in the extraction of boracic acid. Instead of limiting the use of these steam-jets, as in the past, to extracting the salts contained in the exhalations of these natural vapor-vents, the ejection of the steam is stimulated by boring holes. In this way it is possible to obtain powerful jets at a pressure of two to three atmospheres, according to the locality, and in some exceptional instances as high as five atmospheres, the temperatures varying from 150 to 165 degrees centigrade. These jets maintain their force and temperature unchanged for many years, and they are not affected even when other openings, not too near each other, are bored in the ground, proving that they do not influence each other reciprocally, so great is the underlying thermic energy below. In 1905, Prince Ginori-Conti applied this natural steam to a 40 H.P. engine, using only a small section of the Nenella fissure, which is the most powerful "Soffione," the steam ejected having a pressure of five atmospheres.

The results obtained during several years of experimentation were satisfactory, so that he continued to make larger and deeper borings, measuring the force of the steam ejected; combined, this force could operate engines of many thousand horse-power.

In 1912 an experiment was made, very wisely on a more modest scale, but sufficient to obtain conclusive results, for which a 300 H.P. turbine-alternator was used.

Later, because of the enormous increase in the price of coal, the Prince decided to exploit the thermic energy of these soffioni on a much larger scale, but as other substances are emitted with the steam, among them sulphuric acid, which corrodes metals, particularly iron, and therefore the pipes in which the steam was to be collected, he attempted to use this steam only for heating. Three turbine-alternators of 3,000 kilowatts each were installed, fed by boilers at low pressure not heated by coal or other combustible fuel, but by the natural steam, superheated to 165° C., issuing from these soffioni and piped and carried to the boilers.

To-day the works at Larderello have a central plant of 16,000 H.P. operating without interruption and distributing current to Florence, Livorno and Grosseto; its capacity is soon to be increased.

STEAM TRAP

AVOID WASTE

The waste of steam means the squandering of money. Even if steam were cheap, it would be prodigal to waste it; but, now that steam is costly, there is no excuse for not installing SARCOS.

SARCO

saves steam at every essential point. SARCO performs this work as no other steam trap can. As efficient as the best, its small size and novel construction render SARCO capable of being placed at any needed point—and at a remarkably low cost. It never leaks and won't freeze. Several hundred thousand SARCOS in use tell the story.

Investigate our free trial offer and convince yourself.

For Severe Service

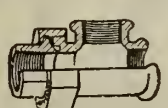
JEFFERSON UNIONS

Pumps—frequently hard to reach—must chug away hour after hour, day after day, without stopping and without attention. Leaky unions have no place in power plant service.

JEFFERSON UNIONS are particularly adapted to meet successfully the most severe tests of service. The Brass Seat Ring makes the brass-to-iron joint which will not corrode and is easily disconnected, no matter how hard or how long the union has been set up. The Spherical Ground Joint makes possible an absolutely tight joint, even though the line is not exactly straight on account of settlement or any other cause.

There are many other reasons why "JEFFERSONS" should be in your plant. They are not "just" unions and the name JEFFERSON stamped on the nut protects you from the doubtful variety. You'll find it mighty difficult to plug a leaky joint with a "just-as-good" promise.

Jefferson Swing Union. Allows widest variety of connections, ranging from a slight offset up to 90 degrees. For angle connections that cannot be made with simple elbow unions.



Jefferson Union Tee, with union on outlet. Has union end threaded either male or female. Should always be used where a union is desired near a tee.

All Male Union Saves two pipe joints between two female threaded parts.

Your Jobber will be glad to show you his stock of "JEFFERSONS." Your inspection will convince you of their merits. Write to-day for our Catalog "UNIONS" which shows the complete Jefferson Line.

WILSON FEARED THE BRITISH

THE American President crossed the Atlantic in the first place with the idea in his mind that his ideals would be thoroughly in accord with those of the French statesmen; but he was rather afraid of a conflict with the British delegates. He found in reality that his plan for peace terms was as far removed from the French plan as the two poles. Then he crossed to London and was surprised to find that the ideas of the two Anglo-Saxon powers were identical.

This situation, according to J. W. Dafoe in the May issue of MACLEAN'S MAGAZINE, explains much that has developed at Versailles. Further, it contains the promise of a close *rapprochement* between the two great English-speaking democracies for all time to come.

Mr. Dafoe has contributed a remarkably interesting article to this number of MACLEAN'S, lifting the curtain on many of the puzzling situations that have arisen overseas. As the editor of the Manitoba *Free Press*, he is the dean of Canadian newspapermen; as the representative of the department of Public Information on the Canadian Mission to the Peace Conference, he was in a special position to learn what was transpiring. He tells of the really big part that Canada has played in the Proceedings and points out that Canada's status as a nation was firmly established in the eyes of the world when she was allowed separate representation.

A Dozen Other Features---Nationally Important

This May issue is full of articles of unusual significance for Canadian readers.

"SOLVING THE PROBLEM OF THE ARCTIC"
—By Vilhjalmur Stefansson

The second instalment of his remarkable story of the four years of exploration that he undertook for the Canadian Government in the region of the "Pole of Inaccessibility"—a harder place to reach than the North Pole.

"ORGANIZING FOR PEACE"
—By George Pearson

An article of the Great War Veterans' Association by a well-known author-soldier.

"THE CANADIANS IN SIBERIA"
—By Capt. W. E. Dunham

A graphic story of what our forces did in combatting the Bolsheviki, by an officer who has just returned.

"SAFE IN THE SADDLE"
—By J. K. Munro

A review of affairs at Ottawa in which the opinion is expressed that Union Government for the time being is safely entrenched.

The National Idea

The articles in this issue of MACLEAN'S reflect the national idea—Canada's part in the Peace Conference, the political situation at Ottawa, the exclusive report of Stefansson's national explorations, the national organization of our returned men, the work of our forces in Siberia. The reader of MACLEAN'S gets a broad idea of what Canada as a whole is doing The value of this issue— and of all issues —is very great, therefore, from an educational standpoint.
MACLEAN'S is the one magazine that should be selected for young Canadians to read.

Four capital stories by famous authors—W. A. Fraser, Lloyd Osborne, Frederic S. Isham and C. W. Stephens.

The Review of Reviews

An unusually fine array of articles is given in this department. selected from the best in magazines and periodicals the world over. Some of the titles are:

Planned to Destroy British Fleet.
How Mackensen Was Caught.
Events of War Foretold by Stars.
What is Life Like Beyond the Grave?
A High-born Bolshevik.
The New Life in Dry America.
Germans Were Ready to Capitulate.
Japan's New Foreign Policy.
The Many Kings of Jerusalem.
Is British Foreign Office Against League?
Ambassador Tells Story of Peace Ship.
Hindenburg—After the Armistice.

GRATON & KNIGHT
Standardized Series
LEATHER BELTING

Power--and the Right Material

Leather is the right material for belting. It is firm. It is strong. It has permanent power of expansion and contraction. It is tough, but it yields in the right degree, at the right time. It is easily and repeatedly spliced or repaired. It stands mauling by shifters. Side-slipping won't fray it. Even after long use it can be cut into narrower belts and goes on with its good work.

Graton & Knight Standardized Series Leather Belts are made to give the longest possible service at the smallest possible cost. Those who use them say that they do.

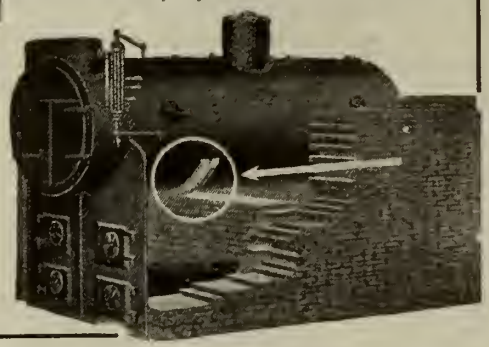
HINTS TO BUYERS

NATIONAL Boiler Girth Seam Protector

Protection means longer life and greater efficiency

If your Boiler is not Fire-cracked it eventually will be. Prevent this by putting on a National Boiler Protector. You will save cost in repairs and prolong life of the boiler. All new boilers should be protected. If your girth seam is giving you trouble at the present time, have the seam caulked up, attach one of these protectors and the seam will remain absolutely dry thereafter.



Guaranteed for one year. We make protectors for patches and all styles of boilers. For full particulars, write—

BOILER INSPECTION

The Steam Boiler Act, Chapter 252 R.S.O., 1914 With Amendments Chapter 58—6, George V.

STEAM BOILERS.

All Steam boilers constructed for use in Ontario must be built from designs which have been approved and allotted a registration number by the Steam Boiler Branch.

Used boilers, boilers sold or exchanged, and unregistered boilers brought into the Province must be inspected prior to being put into operation.

Notice of repairs to steam boilers, stating the nature and extent of same, must be sent to the Steam Boiler Branch, and should such repairs be considered extensive by the Chief Boiler Inspector, the boilers will require to be inspected.

In each and every case the inspections must be made by Inspectors authorized to inspect boilers under the Steam Boilers Act, who are employed only by the Steam Boiler Branch of the Department of Public Works. Official certificates with the maximum working pressure stated thereon are issued to the owners of the boilers so inspected.

STEAM PIPING.

Drawings and Specifications of all high pressure steam piping must be approved and registered by the Steam Boiler Branch before any work of installation is commenced. The drawings submitted should show clearly the dimensions and layout of the main steam lines. Full particulars should be given as to the material used in the construction of the piping, and all valves and other fittings used in connection therewith must be of approved make.

Any deviation from the above requirements shall be deemed a violation of the Steam Boilers Act.

All communications in this respect should be addressed to the Steam Boiler Branch, Department of Public Works, Parliament Buildings, Toronto.

HON. F. G MACDIARMID.
Minister of Public Works and Highways

W. A. RIDDELL, M.A. Ph.D.,
Supt. Trades & Labour Branch

D. M. MEDCALF,
Chief Inspector of Steam Boilers.

Voorhees Rub-Steel Valves

"The Valve with a backbone"

Are without an Equal for

Deane of Holyoke Condensers

or Suctions on Paper Machines

Softest high-grade rubber as seating, supported by an inseparable **steel core.** Spring guides and brass bushed stud-holes as above, if desired, or plain faces.

Not a cheap valve, but positively smoothest in action and longest lasting.

This construction in Four Grades for **every** known pumping service.

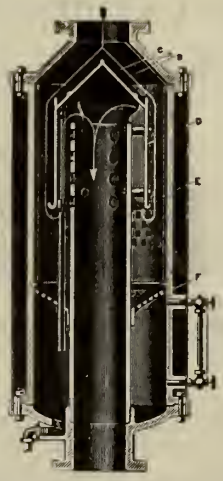
III IMPORTANT THINGS

TO CONSIDER ABOUT A SEPARATOR



I. **THE PLAN**—Is it sensible, will it work, no matter how large the Separator or how well made?

II. **THE SIZE**—Is it big enough regardless of plan, will it hold a good dose of water?

III. **THE CONSTRUCTION**—Is it strong enough, are flanges heavy, how will it look by the side of a nicely finished engine? Send for catalog and note these points in

Sweet's Separators

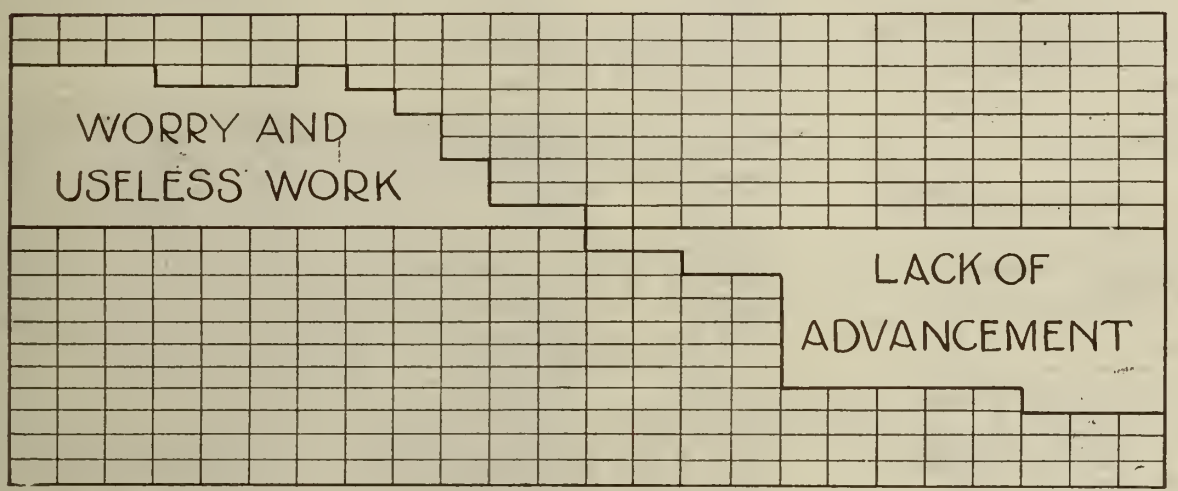
Let the C.A.S.E. Smooth Out Your Load Curve



Remove The Peaks of Worry And Unproductive Labor And Build Up The Valleys By Working For Your Advancement

A man who is thoroughly grounded in the practice of his profession, who is free from personal worry and trouble, overcomes the many difficulties besetting the path of the operating engineer with little labor and in a manner ensuring his advancement.

The successful man owes his success to a wise appreciation of the advantages and mutual help offered by association with those in the same field of endeavor. To join an association having for its objectives the welfare of the engineer in things mental and material, his advancement in knowledge and skill, his protection by provision for sickness and distress is to take advantage of an opportunity indispensable to all who hope to better themselves.

If you are interested in such an organization and live where less than fifteen engineers are located, send for a copy of our constitution and application blanks for admission to nearest branch lodge. If there are more than fifteen engineers in your community, get together and send for particulars regarding formation of a branch lodge.

J. H. HALE, General Secretary,

15 Tons of Coal FREE

Mr. Engineer, does a saving of 15 tons of coal in every 100 tons interest you? This is an immediate and permanent result that comes from the installation of the

JONES UNDERFEED STOKER

It also effects a big saving of labor, automatically maintains a unform pressure, and responds instantly to load fluctuations. Everything that should be burned to generate steam is consumed — this means no fuel waste.
And there are many other advantages in using the Jones Automatic Stoker.

Serves day in and day out with very little attention.

Ask the user. We'll gladly put you in touch with some in your locality.

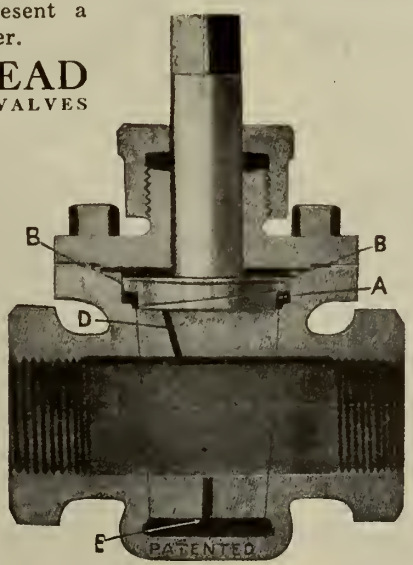
Jones Underfeed Stoker Co.
Limited
37-41 Britain St. Toronto, Ont.

Why Permit Leaks in Your Air Lines?

Those cumulative leaks past your present globe and gate valve amount to a total of many cubic feet per minute and represent a dead loss in power.

HOMESTEAD
QUARTER-TURN-VALVES

are tight and will stay tight under any specified pressure up to 5,000 lbs.
Homestead Quarter Turn Valves not only give assurance against leaks, they save time too. They can be fully opened or closed by just one-quarter turn of the handle.
You can use them on all air, steam, water, oil, gas, acid and other lines. Made in straight-way, 3-way, 4-way and angle patterns; in brass, semi-steel and special acid resisting bronze; either screwed or flanged pattern.



Homestead Valve Mfg. Co.
HOMESTEAD, PA.

FOR REMOVING SCALE

from Babcock, Stirling and other Water-tube Boilers and Evaporators also for Lancashire Boiler Scaling and Rust Removing—there is no tool made to equal my

'SKATOSKALO'
Pneumatic Tube-Scaling Tool.

Simple, strong, speedy, reliable---these words describe its efficiency

Jenkins Bros

Pay You to Make a Change!

Are your pipe lines equipped with ordinary valves? Are they giving faulty service? It would pay to make a change. Adopt a make of valves that have stood the test of time and shown themselves to be thoroughly dependable year in and year out—adopt

Jenkins Bros. Type "K" Brass and Iron Body Gate Valves

—the Valves with the DIAMOND Trade Mark. It is the sign of valve dependability. When you adopt valves bearing the DIAMOND you may rest assured that you have done the utmost to secure perfect valve service.

Type "K" Brass Gate Valves are made of new high-grade metal. The body, trimmings and working parts are strong, and well proportioned. Type "K" Iron Body Gate Valves, too, excel in design and construction; they are leaders in their class.

Jenkins Bros.' Valves are approved by Department of Public Works in Ontario and Western Provinces. Stocked by first-class dealers everywhere. Catalogue No. 8 free on request.

MORRISON'S
High Pressure Injector
Is the Acme of Simplicity

And it works under a greater range of pressures than any other injector on the market, operating perfectly on steam pressures from 20 to 220 lbs. It delivers hot water to boiler at 160 degrees to 212 degrees Fah., according to temperature of feed water and steam pressure. 200 degrees to 212 degrees can always be delivered at nearly all pressures over 50 lbs., by throttling suction valve and delivering the minimum capacity.

Over 40 years' experience and continuous effort to produce steam goods for far-reaching service and satisfaction and an unconditional guarantee stands back of every line that we sell.

THE SCOOP CONVEYOR

The Scoop Conveyor Keeps Equipment Moving

Two or More Scoop Conveyors Make a Flexible Arrangement

Does the Work of from 6 to 12 Men

It has proven to be one of the greatest labor and time savers in storing and reclaiming, in loading and unloading cars, trucks and wagons. It keeps equipment moving. Enables men to work faster and easier. Eliminates much shovel and wheelbarrow work. Does three to five days' work in one.

The Scoop Conveyor has been adopted by over 1,000 leading American manufacturers, contractors and coal dealers because it is durable, light, compact, easily moved around and low in cost. About one-half of our sales are "repeat orders."

It is called "Scoop Conveyor" because the carrying belt receives its load over a scoop which can be pushed or completely buried into the material to be conveyed.

O.K. for Time and Labor Saving in Any Plant

Steam Trap Losses

Should Be Classed as Unnecessary

Steam trap losses contribute largely each year to plant operating cost. In terms of lost time, too frequent adjustments, blowing off, steam leakage, they represent repeated waste. These have been entirely eliminated—and time losses changed into steam savings — where the Johns-Manville Steam Trap is used.

This trap has but three parts—a body, bushing, and hollow ball. When there is no condensate to discharge, steam pressure in the trap holds the ball against the discharge orifice—the only point where there's unbalanced steam pressure. As water flows into the trap, the ball is rolled up, the unobstructed orifice is exposed, and water is discharged. This discharge is continuous as long as water flows to the trap. If air is present it is drawn out through vortices formed at the discharge orifice.

There are no levers, counterweights, springs, or other 'fixin's." It is the most simple and efficient trap made, and absolutely tamper-proof. Ask our nearest branch for special bulletin—it can solve your trap troubles.

BOILERS

Waterous Horizontal Return Tubular Boilers are unexcelled for use in municipal power and pumping plants and for the production of steam for general heating purposes.

They are economical of fuel—carry a big reserve steam pressure for use in emergencies — can be used with hard and dirty water and are readily cleaned and easily taken care of. They cost little new—their upkeep and maintenance expense is negligible.

We build all sizes from 40" x 10' to 72" x 18', and supply them complete for any installation, whether for power production or for heating systems.

Our numerous installations in Provincial and Municipal institutions throughout Canada vouch for the quality of our product.

Waterous

BRANTFORD, ONTARIO, CANADA

"Be Sure the Jeffery Pivoted Bucket Carrier is Included in the Budget," says the Chief Engineer

"You know that ever since the war started what a hard time we've had to keep men in the power plant. You see they did not like the hard, dusty job of wheeling ashes and with the opportunity of having easier work and better wages, you can't blame them for getting out.

"The tremendous job of reconstruction will continue to create a great demand for labor. Another point to consider is that we are planning to overhaul the power plant completely. I am sure the JEFFREY Carrier will prove one of the most economical features we have ever installed.

"By the way, we should have Catalog No. 210-2 describing the Carrier on file here. I'll write for a copy to-day."

Nine Points of Superiority

SUPERIOR finish of a valve is not enough. It must be superior in many ways. It must be superior in strength and durability. It must be superior in workmanship. It must stand every test imposed upon it, before passed.

EMCO Composition Disc Valves have nine points of superiority as the accompanying illustration will show.

The design is approved and registered in the Provinces of the Dominion by Inspectors of Steam Boilers for a working pressure of 175 pounds. They are made of the best Bronze Metal. Each valve is subjected to a thorough hydraulic test before leaving the factory.

Look for the word "EMCO" on each valve.

We can make prompt deliveries. Write for prices, etc.

Registered in the following Provinces as follows:

TALBOT

Contra-Flow Steam Boilers

(Equipped with Crude Oil Burners)

SAVE ONE-SEVENTH THE SPACE OF THE ORDINARY BOILER.

NO BRICKWORK IS NECESSARY.

COST OF OPERATION LOWER THAN ANY KNOWN POWER PRODUCER.

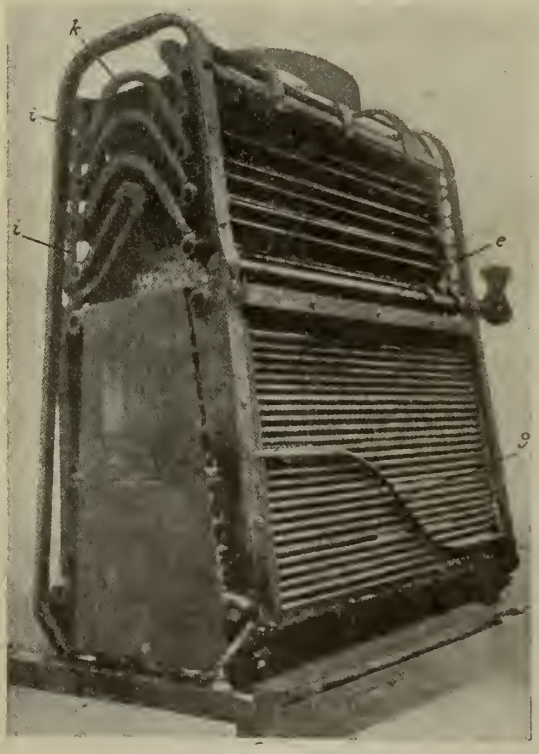
Water enters near the stack and leaves in the form of steam near the furnace.

No water drum. Circulation is through water tubes and is forced at a high velocity by means of a pump.

No Steam Drum.

By preventing gravity circulation the steam is drawn directly from the lower tubes.

The boiler is internally fired, and hence self-contained. Feed water and fuel burners are automatically controlled to adjust the boiler to widely varying demands for steam.



Head of Boiler Casing Removed

Tubes easily replaced under reduced steam pressure. Write for Catalogue B.

Cochrane Heater and Receiver for use with exhaust heating and drying systems.

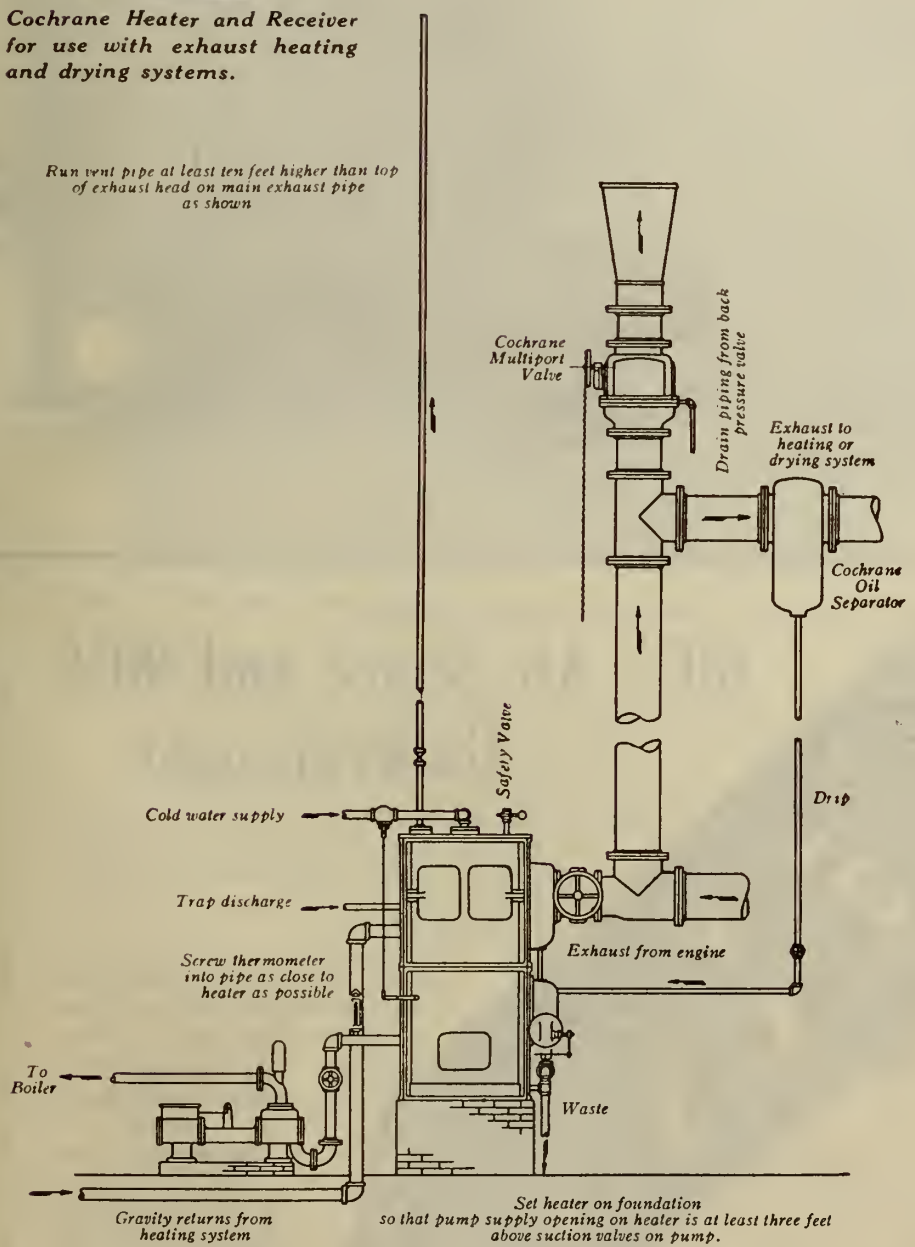
Value of a Cochrane Feed Water Heater

Heating boiler feed water by means of exhaust steam effects a very considerable saving in fuel. The heat imparted to the water in the feed-water heater takes the place of an equivalent amount of heat from fuel on the grates. If the water is heated from 60° to 210° F., the fuel saving amounts to, approximately, 14%, or 1% of fuel is saved for each 11° F. rise in the temperature of the water.

The importance of having the right kind of feed-water heater is shown by the fact that a difference of 1, 2 or 3% of the yearly fuel bill will, in most cases, cover the entire cost of a heater of any type. For example, a 500 H.P. plant running 10 hours, 310 days per year, will use about 3,100 tons of coal per year, worth, at $3 per ton, $9,300. One per cent. of this is $93, and if we assume the interest charge on the heater to be 5%, and depreciation, maintenance, etc., to be 10%, making altogether 15%, the $93 or more with a Cochrane Heater will save over a closed heater for instance will justify the investment of $93÷.15, or $620, that is, $93 is the annual charge on $620 at the rate of 15%. If 2% is saved by the Cochrane Heater over the saving by the closed heater, the excess value of the Cochrane Heater over the closed heater will be doubled, that is, it will be $1,240.

No saving of fuel is realized where the water is heated by an injector or by a live-steam purifier, since both devices first draw from the boiler the heat which is to be imparted to the water, whereas in the exhaust-steam heater a waste product is utilized.

The use of exhaust steam for heating the boiler feed water adds to the boiler steaming capacity; since, as part of the heat is supplied to the water in the heater, the boiler is able to make more steam with a given amount of heat supplied by the fuel. Roughly, six boilers and a Cochrane Heater will make as much steam, with less fuel and labor, as seven boilers without a heater.



Run vent pipe at least ten feet higher than top of exhaust head on main exhaust pipe as shown

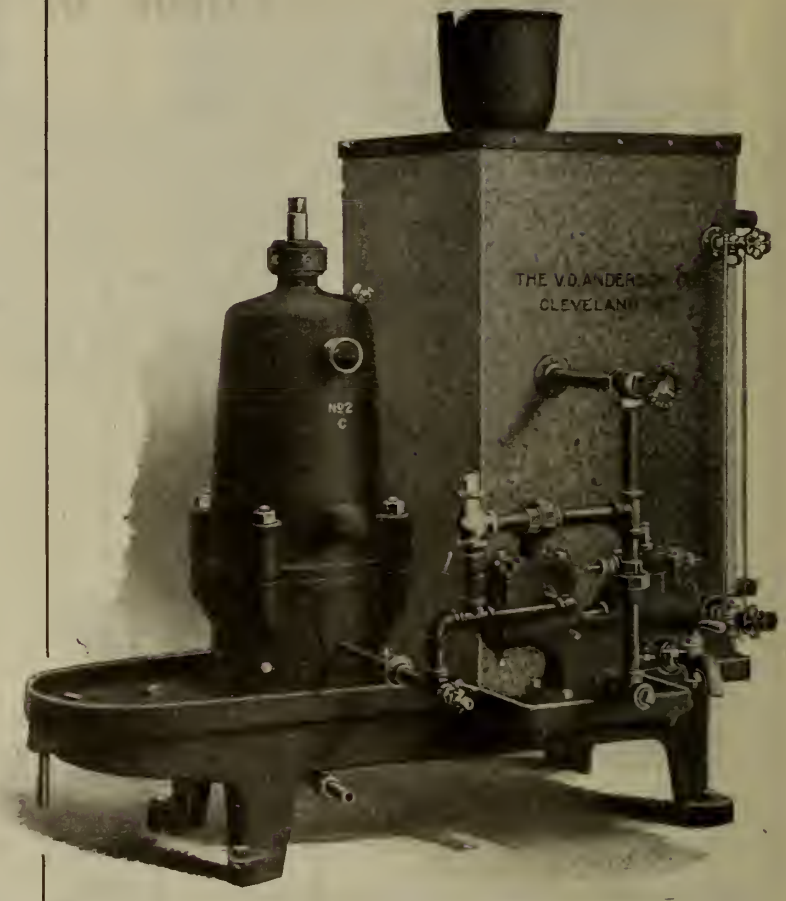
ANDERSON OIL FILTER

Cuts Oil Expenses in Half

How much oil is going to waste in your plant?—lost on the floors, soaked up in rags and waste? Stop this dead loss! Cut your oil expenses in half! It is easily done. Place drip pans beneath engines and machinery. Then pass this oil through the **Anderson Filter** and you will have oil just as **clean** and as **pure** as the new oil you purchase.

You can use oil over and over again with the **Anderson** on the job. No other filter will do the work like it.

Pay you to install the **Anderson** without delay. Let us hear from you and we will give you the full details.



The V. D. Anderson Co.
West 96th St., CLEVELAND, Ohio

Cyclone Grates

60% Air Space and 90% Underdraught

Insure combustion that is perfect. For this reason soft coal, the highest grade hard coal or cheap screenings can be burned on **Cyclone Grates** with absolutely no clinker formation and positively no loss of fuel energy.

Your engineer can install Cyclone Grates without delay or trouble, and **the 30-day trial offer period is long enough to prove their worth to you.**

GARLOCK PACKINGS

"SPARE THE ROD"

Dust and grit are as injurious to piston rods as inferior and poorly lubricated packing. All styles of Garlock Ring Packing are enclosed in press-board tubes and are packed in cartons that are practically dust-proof, which not only prevents accumulation of dirt and grit on the packing but likewise prevents drying out of the lubrication.

On the blank lines of the label attached to the end of each box of Garlock Packing are entered the name of the rod for which the packing is intended and the order numbers, section number and style number of packing, which enable a customer to reorder a box of packing without remeasuring the rod and without likelihood of making mistakes in specifications.

Our packings are billed at net weights; the weights of boxes and tubes are not included.

Municipal engineers demand efficiency—and insist on economy of operation. Power plant equipment, to secure the approval of public engineers, must measure up to the highest standards.

This 22" COPPUS Turbo Blower in the City Hall at Montreal, Canada, has been burning bird's-eye with economy, and holding steady steam pressure without difficulty for many months. Here, as in thousands of plants the world over, COPPUS Blowers burn cheap coal, save time, labor and money, and greatly increase plant efficiency.

That COPPUS Blowers are recognized as leaders in their line is evidenced in the fact that three-fourths of all the blowers made in America bear our trade-mark. Ask our engineers to show you how "COPPUS Equipment can save you money." Write for Blower Catalog H6.

Canadian Representative: FRICK Ice and Refrigeration Co., Montreal

1,000% on the Investment

Suppose you have a 3-inch brine line in your plant, 120 feet long, carrying brine at 15° F. If it were insulated with the proper thickness of

Nonpareil Cork Covering
For Cold Pipes and Tanks

at least $216.00 worth of refrigeration would be saved per year, figuring the cost of refrigeration at 75 cents per ton.

Now it is not at all uncommon for Nonpareil Cork Covering to give continuous, satisfactory service for at least ten years, if properly installed and cared for. Therefore, during its lifetime the covering would save $2,160.00—which at present prices for Nonpareil Cork would represent a return of over 1000 per cent. on the original investment.

Nonpareil Cork Covering installed in 1903 in the Sinton Hotel, Cincinnati, Ohio. This photograph was taken 11 years later and shows the Nonpareil Cork to be in perfect condition.

This shows clearly the advantage of insulating your cold pipes with a material that is not only efficient at the start, but which will retain its efficiency and will withstand hard service for long periods. Each year that covering keeps the heat out and the refrigeration in, means just that much money in your pocket.

In the 64 page book, "Nonpareil Cork Covering for Cold Pipes," there are complete tables which make it easy for you to figure out how much refrigeration Nonpareil Cork will save in your plant. A copy of the book will be sent free of charge on request.

ARMSTRONG CORK & INSULATION COMPANY

Quality Products Leave No Regrets

York Ice-making and Refrigerating Machinery is not made to fit the price. We have a standard of quality and service which has been maintained ever since the York Organization was started.

It is betraying no secret to say that many owners of ice-making and refrigerating plants have expressed to us, by word and letter, their keen regret at having turned down a York contract because the price seemed too high.

Price is a poor gage to use in buying such important equipment as Ice-Making and Refrigerating Machinery. Confidence is a better one. You know from your own experience that business born of confidence begets new business.

No customer can truthfully say that the York Organization ever tried to take advantage of him. It is on this basis that we have been selling our products, and it is for this reason that we have been successful.

An inquiry from you will be appreciated. You are not obligated to buy York equipment until you are satisfied as to its quality and our good intentions.

Pure Corkboard

Made in Canada

A New and Important Source of Supply

All buyers know that the sources of supply of pure Compressed Corkboard and Granulated Cork are few—too few—and the output entirely inadequate at times—an unhealthy situation for the buyers.

Therefore, you have special interest in this *new* and *important source of supply,* large in volume, fine in quality and right in price.

It offers you added *security* both as to *cost* and *deliveries.*

Pure Corkboard is now a necessity to the refrigerating industries, which use many millions of square feet yearly in the insulation of more than eighty per cent, of new construction and repair work.

We are prepared to handle your complete requirements, either for material only or installed in your building. Write us to-day and we will gladly give you full information and quotations.

Firing that is Different

WITH the RILEY STOKER the coal is fed—the fire cleaned—the ash discharged, *continuously* and *automatically*. All done without waste or effort, efficiently and economically.

It is not only the things the RILEY STOKER does but the way it does them. For instance, when steam is wanted quickly and time is precious, you can get this steam instantly and economically by increasing the motion of the grates.

With the first turn of the cranks the grates start moving—the whole fuel bed is thrown into action. There is no watching or waiting—poking nor slicing—the stoker responds instantly and in two or three minutes the boiler will be operating at 200 or 250% of rating.

It is this kind of flexibility that saves not only for the central station but for the industrial plant.

The Quality Standard That Produces "Plus Service" Belting

The only sure way to get satisfactory service is to buy products of known worth.

In Dominion Rubber System Belting, the worth is known because every ounce of material—each individual operation and each finished belt must test up to the highest quality standard ever made for belting.

From the time the materials come into our factory until the belt is running on your pulleys, there is no chance of your getting anything but "plus service" belting.

This is the result of over fifty years of belt making experience and research by the oldest, largest and most completely equipped rubber organization in Canada.

The rubber that goes into Dominion Friction Surfacing Belting is not a mere waterproofing substance—our chemists have given it a far greater value by making it into a friction compound that prevents practically all power wastage on the pulleys.

"Plus service" includes the free technical advice of our belting engineers who are ready to help you with your transmission and conveying problems without placing you under obligation to us.

A phone call, wire or letter to our nearest branch places all of our facilities at your disposal.

"The Only Way"

Efficiency—that's the word. But it must become a reality in equipment and service, otherwise it is meaningless. We find that the engineers are definitely interested in everything that will contribute to their personal efficiency in knowledge and mechanical achievement. Every man wants to be and do his best. The day for the man who "don't care" is gone.

Our investigations have resulted in the conclusion that the editorial and advertising pages of POWER HOUSE have definitely contributed to the development of the engineer. We *know* of many instances where the advancement of men was the result very largely of their studying the editorial and advertising pages of POWER HOUSE. They have said so.

A well-known engineer in Hamilton, Ontario, wrote us on April 10, as follows:—

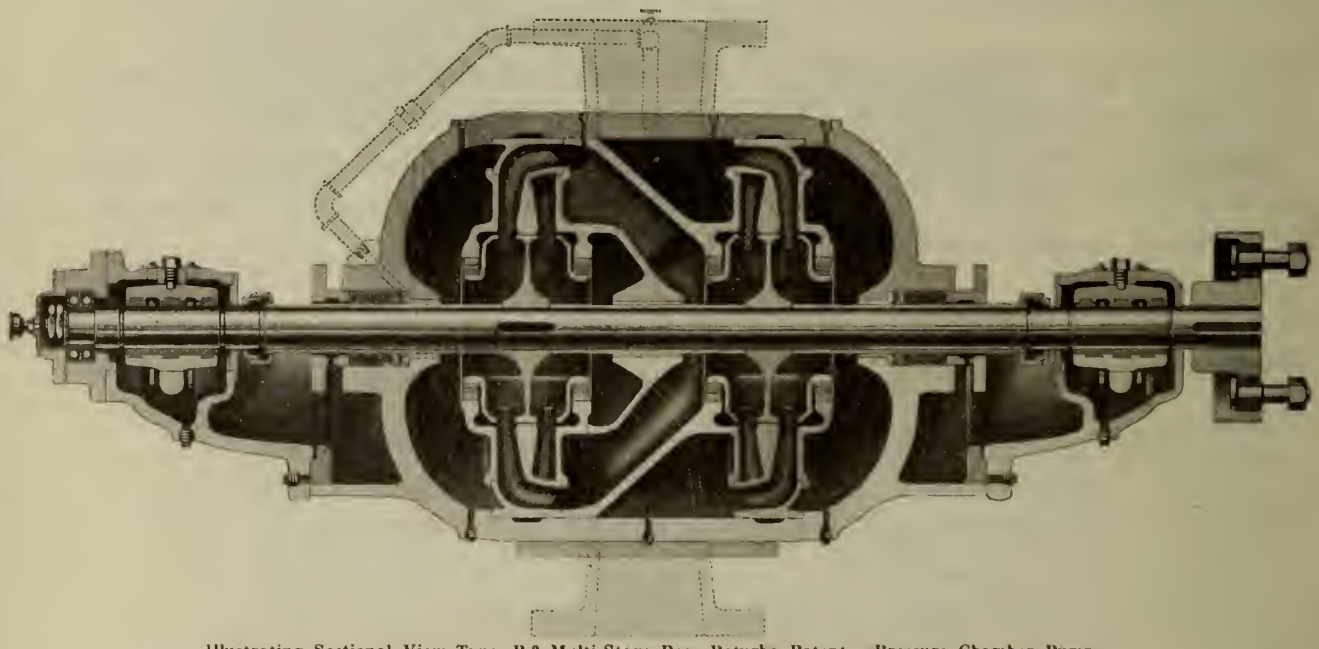
> *"I think the advertisements are good and I read them all the time. If it were not for the advertisements an engineer would not be able to keep up-to-date on new equipment. It is about the only way that we learn about anything new. Circulars are mostly kept in the offices."*

The latter part of this letter is significant—and shows the value of advertisers using their space for the purpose of presenting the merits of their products—the story really reaching the men who ought to be acquainted with the name and line. The engineer's influence on the buying of equipment must be appreciated. Their opinion is largely the basis of decision on the selection of equipment. The other day we saw two engineers in the office of a leading manufacturer of boiler room equipment, and *they* were making the decision regarding the merits of the article, and were recommending the purchase to the general manager of their plant. They were both readers of POWER HOUSE and the article was an advertised product. POWER HOUSE is the reader's one sure avenue of reliable information regarding efficiency in equipment and service.

REES RoTURBo

Pumping Machinery

Is in use all over the World in Waterworks, Mines, Power Stations, Irrigation Works, Pulp and Paper Mills, Salt, Chemical and General Industrial Plants where highest efficiency, reliability and the best class of Engineering are demanded.



Illustrating Sectional View Type, B.2 Multi-Stage Rees Roturbo Patent Pressure Chamber Pump.

REES RoTURBo Pumps provide a high and sustained efficiency over a wide range of duties. This means a very noticeable saving in power costs.

The Self-Regulating feature of RoTURBo design is responsible for this saving, and this same feature protects your Prime Mover from overloads on a decreased pressure head, eliminating expensive delays and costly repairs.

Our RoTURBo Pump and Condenser Catalogues, full of valuable information, are yours for the asking.

The Plant of the Western Canada Power Company

A Hydro-Electric Plant in British Columbia Operating at 125 ft. Head, Supplies Vancouver With Power for Industrial Purposes—Provision for Extension Has Been Made

By F. C. PERKINS

THE accompanying illustrations show the hydro electric plant of the Stave Falls water power development in the Province of British Columbia and the hydraulic turbines and electric generators in service. It may be stated that the Western Canada Power Company, Limited, was formed for the purpose of supplying power for industrial purposes in Vancouver and the vicinity, so as to encourage the establishment of factories, and in sufficient quantity to meet any demand that the growth of Vancouver may develop. Several years ago the company took over the property and franchises of the Stave Lake Power Company, Ltd., which had secured a charter from the Government of the Province of British Columbia, giving it the right to develop power on the Stave River, and to distribute power over the whole of the district surrounding Vancouver, and had also secured franchises for the sale of power for industrial purposes in Vancouver and New Westminster.

The Stave Lake Power Company had in the course of several years done a considerable amount of preliminary work at the Stave River, including the establishment of a gauging station, the building of roads and camps, and the partial construction of a log sluice dam. The Western Canada Power Company, Ltd., commenced the construction of a 50,000 h.p. power plant, and the first section of this house, comprising two units of 9,000 K.W. capacity each, was completed and power was delivered in Vancouver on January 1st, 1912.

POWER HOUSE, STAVE LAKE.

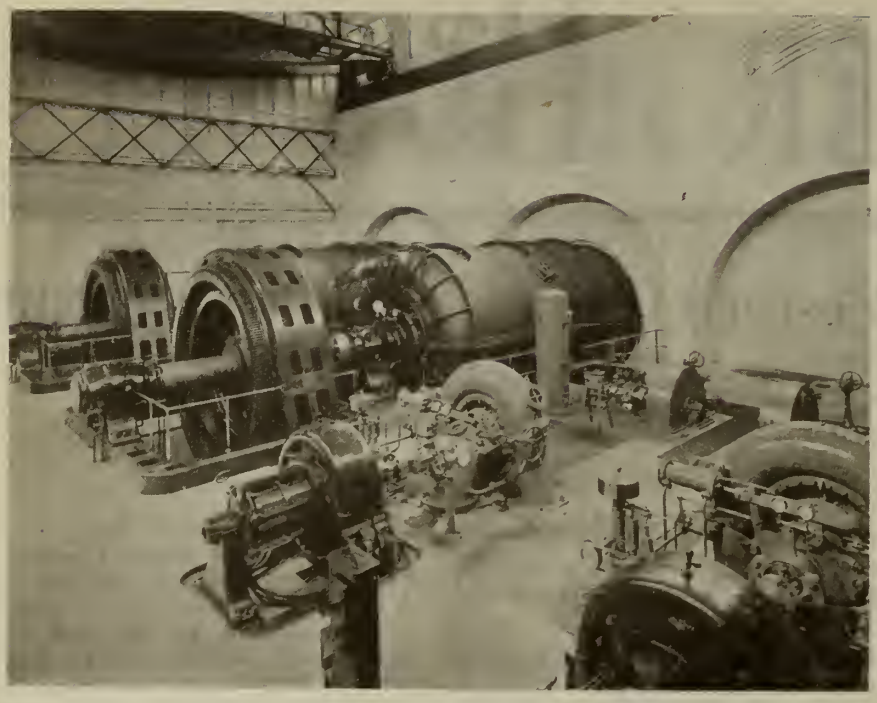
The site of the power development is at Stave Falls, about six miles north from the junction of the Stave and Fraser Rivers at Ruskin, B.C., and thirty-five miles east of the City of Vancouver. The mountains forming the watershed are granite; they rise high above the timber line, and are covered with snow and small glaciers. The upper river is a large glacier-fed stream, and several smaller streams empty into the lake, some coming direct from the glaciers on the high mountains on the west side of the lake.

It is of interest to note that the lake is nine miles long and about a mile or more wide. The east and west shores are precipitous, but at the head and foot there are large areas of low lying land, which are flooded during high water. From the foot of the lake to the Stave Falls the river is seven miles long, about two miles of this having been rapids, with a total fall of 11 feet, the rest being navigable at all stages of the river and having practically no fall. At the falls and the rapids, in the immediate vicinity of Stave Falls, the river drops 80 feet, and then continues on its course over a series of rapids for a distance of four miles, finally debouching through a narrow granite gorge into a tidewater basin, where it joins the Fraser River.

The total fall from the original low water level of the lake to tidewater was 225 feet, and when the dam which has now been constructed, has been increased to its full height, the water will be raised 35 feet above the low water level. The dam forms a lake extending from Stave Falls to the upper end of Stave Lake, a distance of 18 miles. The area of the lake at the present height of the dam is about 13 miles, and when the dam is completed to its full height the area will be 24 square acre feet, which is large enough to store the flood water so that the total mean flow of the river will be made available for the generation of power. Daily gauge records of the flow have been kept for over six years; during the past three years a careful series of hydraulic observations have been made, and the mean flow has been found to be 3,500 cubic feet per second that can be utilized for the purpose of generating power.

The total fall from lake to tidewater will eventually be made use of in two power houses; the upper plant, which is now in operation, utilizing 125 feet maximum and 105 feet minimum head, and the lower plant utilizing the balance. The site of the first development was chosen in the vicinity of Stave Falls; at this point the river is divided into two branches by a rocky island half a mile long, admirably adapted for the construction of forebay and intake works, while an old channel, known as the Blind Slough, with a rocky bed some 600 feet wide at a higher level than the bed of the existing river, presents a most excellent site for a dam to provide for the flood discharge.

The second development will consist of a dam 160 feet higher at the highest point, built in a narrow gauge between to form a reservoir about three miles long, backing the water up to the tail-



STAVE FALLS DEVELOPMENT, GENERATOR ROOM, STAVE FALLS POWER HOUSE.

race of the upper plant. The power house will be located to the east of the dam, with its tailrace on tidewater, within sight of the main line of the Canadian Pacific Railway, and the penstocks for the turbines will be laid in tunnels about 1,600 feet long.

This remarkable power plant, as it now stands, consists of a sluice dam 40 feet high, provided with five sluice ways 22 feet wide to take care of the flood discharge; a solid concrete intake dam, two 14 feet 6 inches steel penstocks, with provision for two more, a power house, with two 10,000 K.W. units and provision for extension of two more, and a tailrace channel 1,500 feet long, excavated in the old bed of the river.

The sluice dam, which was partially built by the Lake Stave Power Company, consists of four concrete piers 8 feet wide, with two abutment piers, the spaces between the piers being filled with 24-inch stop logs, 24 feet long, which can be removed by means of water. The intake work consists of a solid concrete dam about 70 feet high at its lowest point, imbedded in which are the four steel penstocks, which are belled out to 19 feet diameter at their entrance, and taper down to 14 feet 6 inches in diameter where they leave the dam. The entrance to these penstocks are closed by steel radial gates, closing an opening approximately 20 feet square, and designed to operate under a maximum head of 45 feet. These gates are operated by electric winches set on the top of the dam. There are also two 42-inch exciter penstocks, which are closed by radial gates.

In front of the radial gates are set screens of very large area. No special precautions are taken to protect the screens from ice, as it is a peculiar condition of the Stave River that no ice ever forms, even at times when zero weather obtains for as much as a week. The reason of the non-formation of ice is that there is a large overflow from the forests during the winter months which raises the temperature of the water. These dams are at present built to such a height as to store the water about 7 feet above the original low water level of the lake. They are being raised this year, 1914, an additional 10 feet and next year they will be extended another 25 feet in height. The sluice dam, which is being carried to its full height, will be made into a solid dam, and will no longer be used for flood discharges.

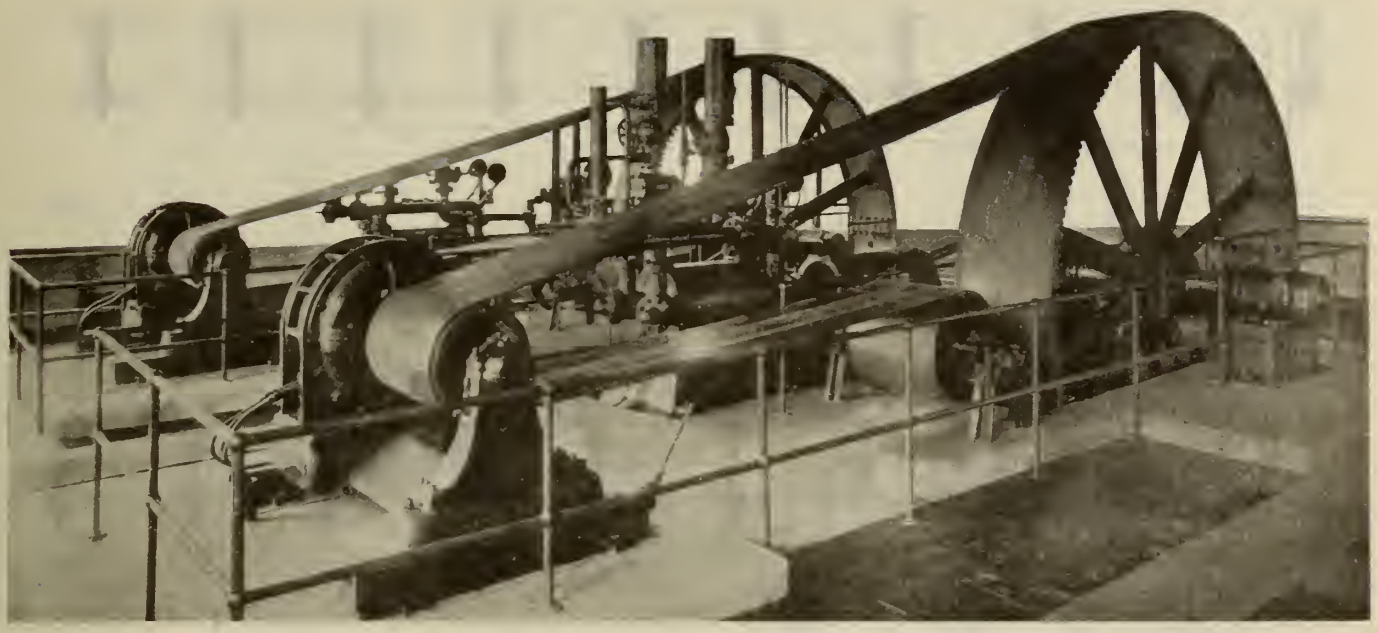
In the new construction the dam which is to be built across the Blind Slough will consist of concrete piers 30 feet high, making 14 sluice ways, each closed by stop logs, which can be removed by an electric winch. Provision will be made in the design of these sluice-ways, so that a stoney roller gate can be placed in any of them if it should be advisable, but the operation of the stop logs has proved so economical and successful for handling floods, that it is not likely that more than one of the sluice-ways will be closed by a stoney gate. The Blind Slough dam will provide for a maximum discharge of 100,000 cubic feet per second. The foundations for the power house were excavated in solid rock. The total quantity of rock excavation for the penstocks, power house and tailrace amounted to 75,000 cubic yards.

A tailrace canal, 70 feet wide, has been designed to run 10 feet deep when all four units in the power house are in operation. In addition to the rock excavation for the tailrace, some 75,000 cubic yards of sand, clay and boulders were excavated by steam shovel. Just below the power house a small V shaped weir was built to hold the water to a proper height to seal the draft tubes. At present the flow of the river is rapid from below the foot of the tailrace, but when the lower plant is built, the water will be backed up to this weir.

The foundations for the power house are of solid concrete construction, and the superstructure is a combined formation of steel and reinforced concrete. The building is 100 feet wide by 90 feet long. The turbine and generator room is 75 feet by 90 feet, and a two storey lean to 28 feet wide houses all the high tension and low tension switches. The control switchboard is on a gallery in a lean-to at the end of the building. The power house is now being extended 70 feet more for the installation of two new units. In the power house are installed at present two 10,000 K.V.A. 3-phase, 60-cycle, 4,400 volt generators, built by the Canadian General Electric Co., driven by two 13,000 h.p. Francis type turbines built by the Escher Wyss Company, of Zurich, Switzerland. Excitation is provided by two 250 K.W. 125 volt generators, each driven by its own turbine, and each capable of exciting four machines.

The writer is indebted to J. T. Johnson, hydraulic engineer of the Dominion Water Power Branch, for the accompanying photographs, and to Engineer G. R. Conway for the detailed information of this Canadian water power device.

STAVE LAKE



Effective Transmission Most Essential to Economy

Treatment of Shafting, Pulleys and Belting is All-Important—Various Details of Designs and Installations, as Well as Operating Features—Care of Belting and Proper Application of Dressing

By J. H. RODGERS

AMONG the many features involved in the problem of production few are more important than that of effective transmission of power from the primary unit to the machine that is performing the work. Very frequently, output is restricted owing to the failure of some part of the power installation, or the neglect in correcting some fault after the same has become evident. Too much attention cannot be given to this essential feature of plant operation. The treatment accorded to shafting, pulleys and belting, should be considered one of the fundamental details upon which the efficiency of the shop is based. No plant can expect to maintain a high average of production unless the transmission is constantly kept in the best condition. To accomplish this it is very advisable—and in large factories almost essential—to place the maintenance of this branch of the work under the supervision of one experienced party, a man that can give his entire time to the work, and with assistants if necessary. Where every machine operator is permitted to repair his own belts, tighten or adjust pulleys, effective operation is a doubtful factor. While it may be true that some men are thoroughly familiar with the peculiar and ofttimes apparently insignificant features relative to belt repair and upkeep, it is nevertheless good practice to have the transmission maintenance in charge of a man or gang especially selected for the purpose. We say selected in preference to appointed, as it is particularly advisable that the men doing the work of installation or repair, should know why they are doing it as well as how they are doing it. The various conditions under which a belt man has to perform his duties enables him from experience to evolve ways and means to maintain the maximum efficiency from the belts and pulleys under his charge.

The compilation of the following article is the result of observation and experience in the use and abuse of transmission equipment, and is here set forth as an aid to those who have, or may have, to do with the installation and subsequent repair and maintenance of shafting, pulleys, belts and accessories. In the unit system of machine operation, where each tool is driven by its own individual motor, the installation of overhead shafting is seldom required, but where the group system is adopted it is invariably a necessity to have a line of shafting to distribute the power to the different machines located about the shop. In general practice of to-day the group drive is so proportioned that the use of long lengths of shafting is vir-

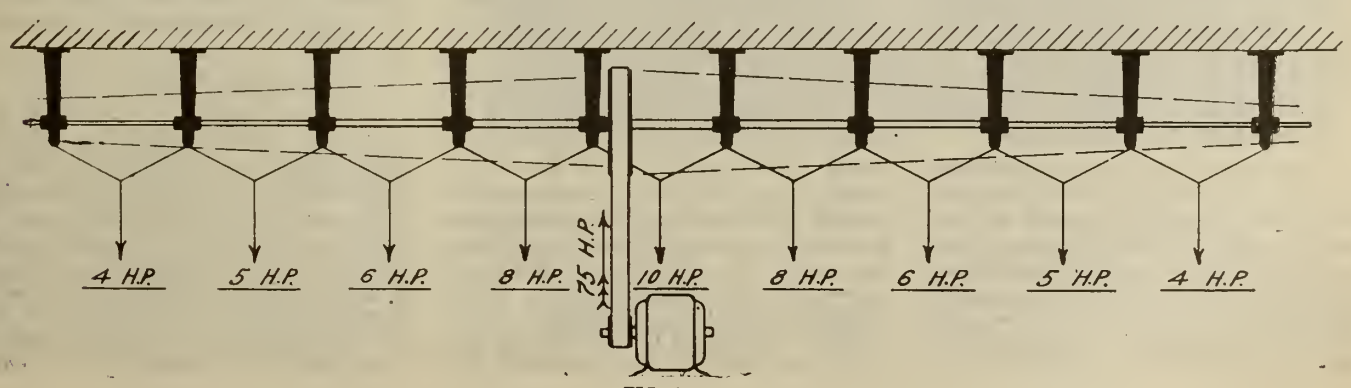


FIG. 1

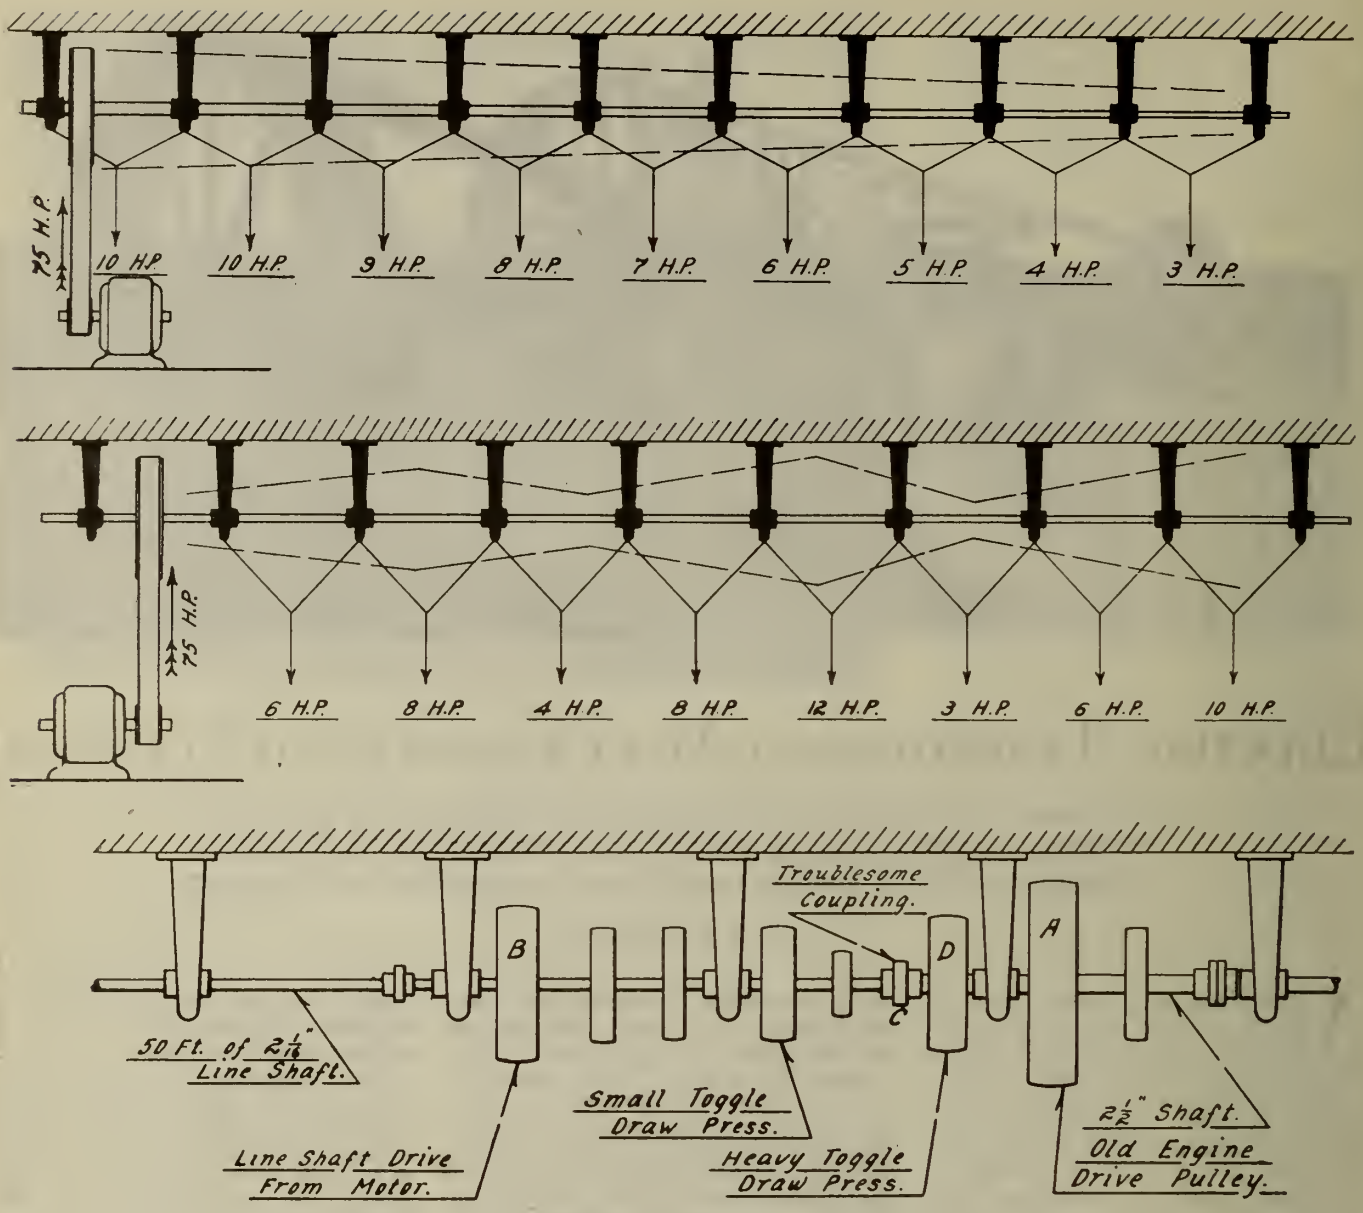

FIGURES 2, 3 AND 4

tually eliminated, and where main shafts of excessive length are used it is considered an economic feature to arrange the power distribution in such a way as to minimize the torque throughout the shaft. This twisting action may often be so great as to develop a grave source of annoyance and may eventually necessitate the rearrangement of the drive to overcome the trouble. Very frequently, an installation of machinery may be made in a plant, or additional units located in available space, with but little thought of the source or distribution of the power required to operate the different machine tools.

Minimizing the Shaft Torque.

In determining the position of the machines in a group, or when adding a tool to the existing equipment, the volume of power required to operate, and the special purpose of the machine, are two factors that should be given careful consideration. If this is not done the efficiency of the machine may fall below expectations, and be prematurely condemned. Wherever possible—and it is advisable in all cases—the heavier machines that require a proportionately high percentage of power for their operation, and particularly in cases where the consumption of power is spasmodically varied from light to heavy load, should be located as near the source of line shaft power as conditions will permit. While no fixed rule can be applied for installations of this character, owing to the fact that no two plants are identical in their layout or production requirements, a general recognition of stabilized distribution would meet the end desired in practically every instance.

It is seldom that the entire power developed by the engine or motor is consumed in the operation of the equipment, so that in initial installations allowance is always made for subsequent units to be operated from the primary line shaft. The character of the motor support is very important, but is dependable upon local conditions. Good results are obtained by locating the motor on the ceiling or on a specially constructed concrete base. The former practice provides more available floor space, but the latter assures a more stable foundation and more accessible for repairs. Where a support of this kind is not permissible, a substantial timber framework may be constructed to carry the motor, which may be located on the floor, wall or ceiling. The fundamental requirement, however, it to have the support rigid enough to eliminate all vibration, a condition that is invariably the progenitor of many motor troubles.

Location of Motor Drive

It is good practice to locate the driving motor about midway of the line shaft length, as illustrated in Fig. 1. When delivering to, or taking power from a line shaft, it is advisable to place the pulley as close to the hanger as possible, and this rule applies in particular to heavy drives or those where the absorption of power is intermittent, such as the operation of machines requiring a flywheel for stability, as in power

presses, punching and shearing machines, and like equipment. In placing machinery in a shop it should be the practice to locate the heavy tools close to the main drive so that the twisting moment

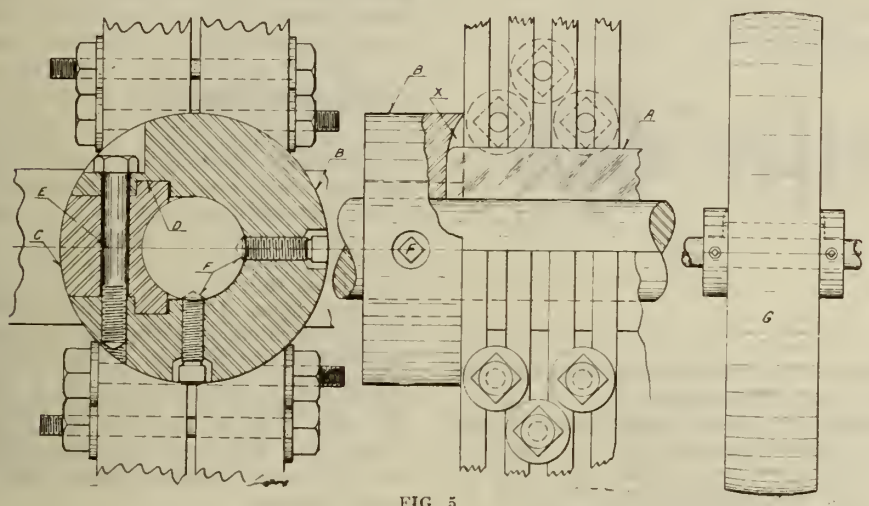

FIG. 5

in the shaft will be kept at the minimum, the lightest tools being situated farthest from the motor. Fig. 1 will serve as a good example of the central drive method; this shows the reducing value of the power delivered when nearing the extreme ends. This, however, is an ideal condition and can only be taken as a guide for an actual installation, theory only serving as an assist to practical adaptability.

When the drive is located at one end of the shaft, as shown in Fig. 2, it is imperative that the heavy machines be placed at the motor end of the shop. The farther such tools are situated from the motor the greater the twisting moment of the shaft and the increased possibility of line shaft. When main shafts are of extreme length it would be well to adopt a reducing size of shaft to aid in overcoming the shaft torque. An example of a line shaft drive that should be avoided is shown in Fig. 3. Here the drive is on the end, the diameter of the shaft uniform throughout its entire length, and the power delivered very irregular, factors that would provide excellent opportunities for inefficient operation. The skeleton lines show the varied fluctuations in the power delivered, and the great possibility of troublesome torque is quite obvious.

Inefficient Installation.

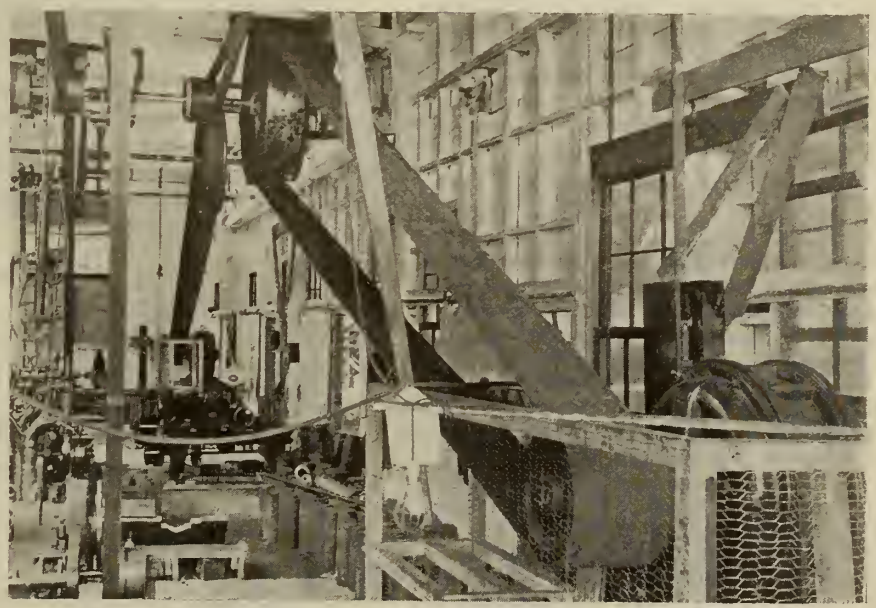
A special instance of ineffective line shaft drive is diagramatically illustrated in Fig. 4. In prehistoric days this shaft was driven by a steam unit belted to the large 6 foot cast iron pulley A, keyed to the length of 2½ inch shaft. The advent of the motor placed the engine in the discard and the new source of power was at the pulley B, the size of the entire line shaft, apart from the length above mentioned, being 2 1-16 inches in diameter. To the left of the drive, pulley B was approximately 50 feet of shafting carrying pulleys for operating various presses and other small tools. To the right were a couple of punch presses and a small draw press. Adjoining the reduction coupling C, and on the larger shaft, was the four foot pulley drive for the heavy drawing press. When the latter was in operation, more especially when on heavy drawn work, the coupling C was a source of constant annoyance, giving out a continual squeak when the full load came upon the press. This particular trouble was laid to the fact that the pulley A was out of balance and had an apparent oscillating motion, due to its poor alignment. Its removal was contemplated on different occasions, but no determined effort was made to do so. It is the writer's opinion, however, that the primary cause of the shaft trouble was the inefficient method of the drive itself, and the location of the heavy draw press in relation to the motor drive.

Cure for Slipping Pulley

In addition to the trouble arising in the coupling C, the pulley D, that operated the large draw press, could not be kept tight on the shaft and would persist in slipping when the extreme load came upon the press; this slip was invariably accompanied by the usual squeak. This pulley was of the wood split type but persistent tightening of the clamping bolts was of no avail. Sand paper and emery cloth was tried between the bushings but only provided a temporary relief. Holes one-quarter inch in diameter were then drilled in the shaft at either side of the pulley and in line, and a 3/16 inch strip of steel placed between the two halves of the pulley, this being the available space after the clamp bolts were tightened. On either end of this strip was a short tit about ⅜ inch long, that entered the holes drilled in the shaft. The clamp bolts were used as a backing to support the steel strip. This served the purpose for a short time but eventually the end tits were sheared off. The final and effective repair is shown in Fig. 5. Two collars B were provided, open on the side for placing over the shaft, and the gaps filled with the piece C, fitted with the tee slots D; the two parts secured by the bolt E. The steel strip A, located as in the previous case, entered a slot X milled in each collar. When in position the collars were secured to the shaft by the set screws F. A general view of the repair is shown at G.

Belts Require Proper Care

Few details in connection with manufacturing receive less considerate attention than that of the belting that transfers the power from the line shaft to the various machines. Many men think that all that is required is a tight belt and all their troubles are over. If the belt is slack, take a piece out and replace the belt. Very good, if this is done with a knowledge of the necessary requirements. Few men will deny the advantages accruing from a well spliced endless belt, but how many of such belts will one see in the average shop, apart



MAIN DRIVE WELL PROTECTED BY GUARD

from those used on the main drives. The general practice on the larger volume of belts used is to cut the belts to the desired length and join by means of lacing or other fasteners. Many types of fast-

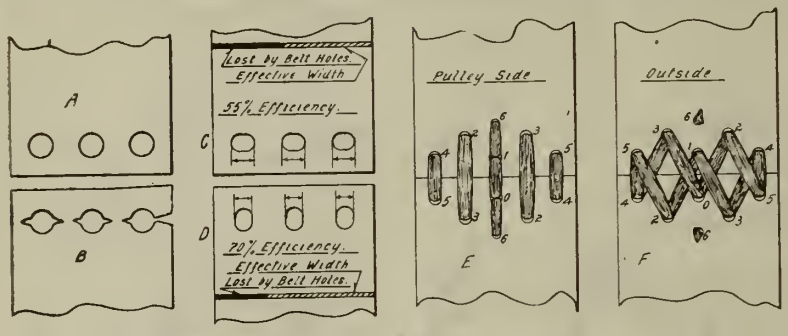


FIG. 6

eners are now in use and are giving very satisfactory results, but few will retain the all-round efficiency of the ordinary leather lace when the joint is well made. One great disadvantage of metal fasteners, particularly where shifting of the belt is to be made by hand, is the dan-

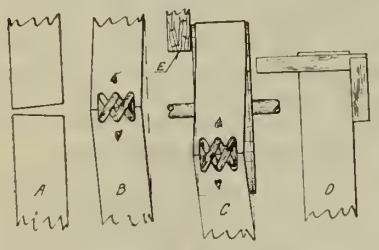

FIG. 7

ger to the operator contingent to the loose end of wire or metal portion. However, where careful attention is paid to such joints they are very effective for continuous drives. Leather lacing, nevertheless, will doubtless continue to be the general practice for belt repairs, owing to its accepted simplicity and general convenience.

Use Small Lace Holes

It must not be taken for granted, however, that all one has to do is to cut off a piece, punch a few holes and secure again with a lace, to obtain an effective drive. The fundamental details of a properly made joint may often seem of little import, but the subsequent operation of the belt may depend, very largely, on the consideration given to these apparently insignificant matters. When making a repair to a belt the beginner will usually make the lace holes of large size as indicated at A, Fig. 6. The inevitable consequence of such practice will be that shown below at B. With very few exceptions a belt will tear across the lace holes and seldom will fail in a direction parallel to the belt length. For this reason it is imperative that the amount of the leather cut out be kept as low as possible, consistent with the size of the belt and the thickness and width of the lace. Where it is necessary to enlarge the holes it should be done as shown at D and not as at C. This is obvious when comparing the resultant efficiency of the belt in each case. The heavy black line indicates the portion of the width cut away by the holes and the shaded line the effective section of the belt. With the same opening for the lace the efficiency of the lower method is 15 per cent. over that of the upper.

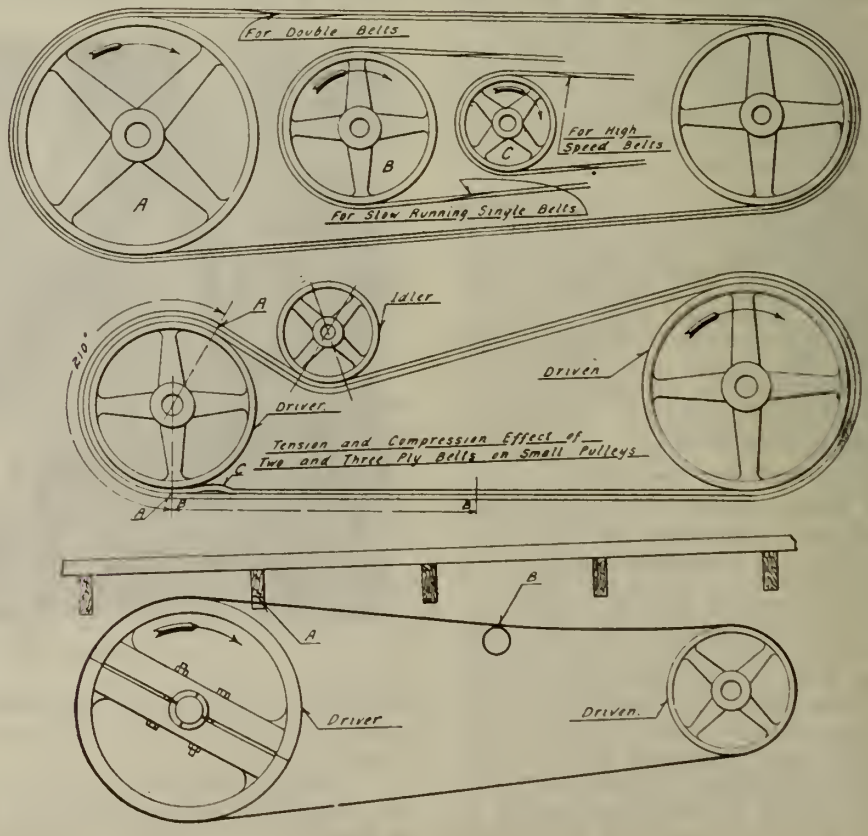
The best side of the belt to run upon the pulley appears to be a debatable question, as many favor the hair or smooth side, while others prefer the reverse. However, as the efficiency of a belt drive relies on the frictional contact between the surfaces it would seem practical that the smooth side would have the preference. Another factor in its favor is that of the recognized fact that the portion of the belt best suited for tensile strength is near the flesh or rough side, and the hardest side best adapted for the compression action; these features being quite evident when belts are operating on small pulleys.

Making a Laced Joint

In making a joint it is advisable to use a thin lace in preference to a thick one. This coincides with what has been said on belt contact, as it is clear that the thicker a lace is the less will the contact be when the joint is passing around the pulley, and in addition the jar will be all the more pronounced. When making a joint the straight lacing should be made on the pulley side. Owing to the different widths of belts no fixed rule can be applied for lacing, but in general the method may be the same for every case. Holes should not be closer to the edge or end than one-half inch, with centre holes spaced accordingly. The best practice is to commence at the centre and work out and back on each side. As a guide the illustration at E and F is given. Starting at 0 and 1 the order is as follows: 2, 3, 4, 5, 4, 3, 2, 1 or 0, both sides of the centre being identical; the locking is performed by passing the free end through a small hole 6, and cutting a short slit to form a hook that will prevent the lace from coming out. This lock should be on the outside of the belt. After the joint is made it may be lightly hammered down with a wooden mallet.

Preparing Belt for Lacing

One of the essential factors of a belt joint is that the ends should be perfectly square with the run of the belt, to assure its smooth running. When cutting a belt the use of a try square, as shown at D, Fig. 7, is always advisable. Without such a tool the tendency is to make an angular cut as at A, so that when the joint is made it has the appearance as illustrated at B. When passing over a pulley the belt develops a tendency to oscillate, and such a condition is very much aggravated when the belt is running a little loose. To prevent it jumping off, a stick



FIGS. 8, 9 AND 10

is frequently secured to some rigid support and extended down at the side of the pulley, as at E. This, however, provides only a temporary remedy for a previous fault, as the weakest portion of the belt—the laced joint—is continually brought into violent contact with this "guide," and eventually the value

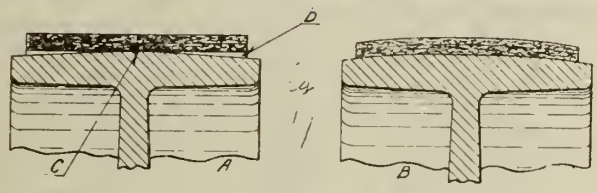


FIG. 11

of the joint is destroyed. Where guides are considered necessary—and they are only required to correct faulty installation or repair—they should take the form of rollers and not as rigid members; this would minimize but not entirely eliminate the source of trouble.

Direction of Travel

Another point that comes under discussion in connection with leather belts is that of the spliced joints, and their relation to the direction of travel. It is quite evident that the thin edge of the lap may show signs of parting after a period of service. For this reason some men contend that the belt should be run with the splice as shown at B, Fig. 8. On this principle the action of the pulley will aid in keeping the thin edge down to its place. On the other hand, some belt men say that the action of the air on the belt surface when in motion tends to lift the edge from its place. As this air action is greatest when the joint is passing around the pulley it would appear that the subject is open to discussion. However, as slow running belts are not subjected to excessive air action it might be said that the method shown at B would be best, and that at C best suited for high speed belts. Irrespective of the advantages claimed for either method, the entire question seems to be one of careful attention in the matter of re-

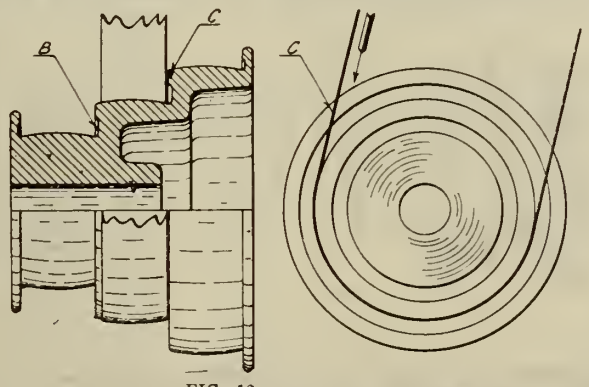

FIG. 12

pairs and maintenance so that faults may be remedied as soon as they are observed.

Avoid Small Pulleys

In double or three ply belts these splices can be run to meet both conditions as shown at A. In the use of double or triple belts for heavy power drives, care should be taken to use pulleys as large as possible, consistent with speed requirements, as effective heavy drivers are not to impossible on pulleys of small diameter. This is quite clear when we consider the lack of flexibility of the heavier belts. Another argument against the use of small pulleys is the imperceptible cheeping action of the belt in making the round of the small pulley. It will be obvious to all that two opposite forces are at work when the belt is on the pulley—that of compression on the inner side and tension on the outside. These forces are neutralized between the curves, but immediately come into action again when the pulley is reached. For instance, suppose the length B-B, Fig. 9, to represent the length of the pulley circumference in contact with the belt. The length of both sides of the belt between B-B will be the same, but not so when this same portion is wrapped about the pulley, as at A-A. If the contraction of the inner side equals the expansion on the outside, the centre length will remain unchanged, but such is seldom the case, so that the tendency is usually to destroy the adhesion of the two layers as shown at C. For this reason too small pulleys should be avoided when using double or three ply belts.

Idlers as Tighteners

The use of idlers is often resorted to, but for the above reason, it is well to have these of fairly large diameter, especially where the idler contact is excessive, as the forces at work are directly opposed to those on the main pulleys, thus creating a destructive bending action in the fibres of the belt. For belt drives of this character it is advisable to maintain flexibility by means of some liquid preparation that will penetrate the fibres of the belt. When idlers are used they are invariably located close to the smaller pulley, so as to increase the arc of contact and likewise the driving power.

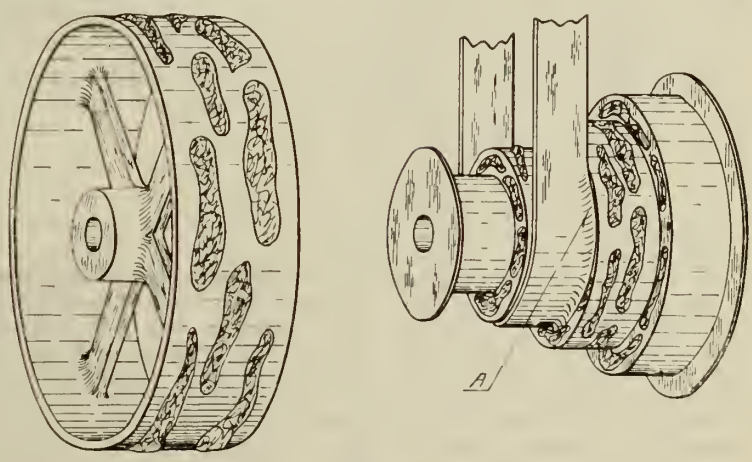

FIG. 13

Keep Pull on Under Side

In the installation of horizontal or oblique drives it is always advisable to locate the shafting so that the pull on the belt will be on the lower side. This will bring any slack on the upper portion of the belt and the sag will add to the lap on the pulleys. To the average

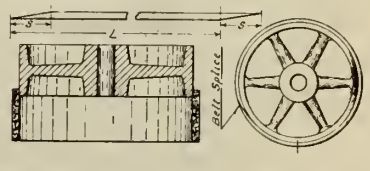

FIG. 14

man a tight belt is supposed to deliver the greatest power, and while in some respects this may be true, much of the power delivered is absorbed by the additional friction on the shaft bearings, so that the effective pull may be less than would have been the case with a little slacker belt. When the centre distance of a drive is relatively short it may be necessary to operate with a fairly tight belt, but in a long stretch a slack belt will give equal, if not better service than a belt that has excessive initial tension.

Have Plenty of Clearance

In many shops particularly those with low ceilings, the shafting may be placed in such a position that belts on large pulleys have very little clearance; in some instances it is necessary to cut a piece out of a beam or joist to allow the belt to operate. Frequently, this cutting is just sufficient to clear the belt, as shown at A in Fig. 10. When the drive is one of a fairly steady or uniform load this may be ample, but if the load on the belt shows a tendency to fluctuate it is more than likely that the belt will flop up and down, invariably resulting in the belt striking the joist. Such action is very detrimental to the life of the belt and especially the lace at the joint, as the rubbing will soon effect its destruction and repairs are required. This also applies to other possible points of interference, as pipes or rods passing either above or below the belt, as shown at B. Where points of interference are a source of annoyance, facilities should be provided to minimize the trouble, such as the giving of greater clearance, or the placing of rollers to prevent excessive wear on the belt or laces.

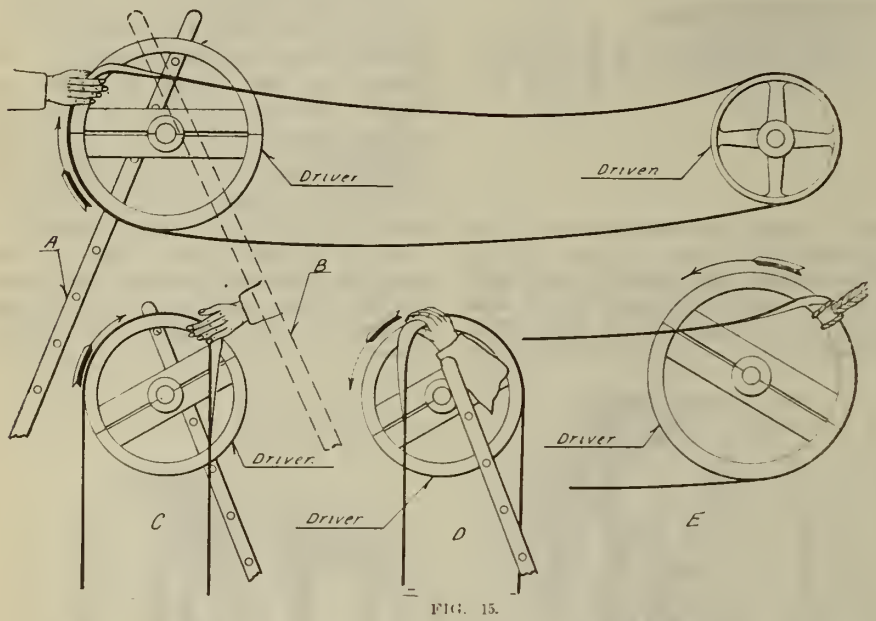

FIG. 15.

Crowning of Pulleys Important

Steady running of belt is essential to effective transmission. For continuous drives, belts are generally run on pulleys that are very little wider than the belt, and to maintain its position in the centre, the pulleys are invariably crowned. This crowning usually consists of two straight tapers meeting at the centre of the pulley face. The amount of the taper varies from ⅛ inch to ¼ inch per foot; that is, a pulley 12 inches wide would be about 1-16 inch larger in diameter in the centre than it would be at either edge. In a straight taper crown, however, it will be seen that the apex C, Fig. 11, forms a definite or pronounced breaking point; nothing very serious possibly, but with a tendency, especially in new and heavy belts, to provide an air space at the edges D. A better plan of pulley crowning is that shown at B, where the surface forms an arc; this method equalizes the bending stresses throughout the width of the belt and makes the surface contact more uniform.

Careful Use of Belt Dressing

To increase the driving power of a belt, or rather to increase the pull, the use of belt dressing is very frequently adopted, and when judiciously applied such dressing may add materially to the effective operation of the belt, but where careless or thoughtless application is made, the practice may not only prove inefficient but very destructive to the belt. The driving power of a belt depends upon its flexibility and adhesive qualities, therefore the object of a belt dressing must be such as to retain these essential features. The adhesive action may be increased by careful application of belt dressing, but pliability can only be attained by a liquid or semi-liquid preparation that will penetrate the pores of the belt. When properly used a surface dressing will very often pull one out of a hole, but if constant applications are required to maintain the "pull," steps should be immediately taken to eliminate this apparent necessity, which is generally nothing but neglect in maintaining the belts or pulleys in good working conditions.

Destructive Practice

Where the surface dressing—or as it is often called, the "belt stick"—is freely used, it is not uncommon to see pulleys in the condition shown in Fig. 12, with large patches of the dressing clinging to the face. As said before a belt derives its power from frictional contact with the pulleys and while the pull from a well "dressed" belt may seem better, the general efficiency has not been increased. This may be made more clear when one realizes the air pockets that must be formed between the patches on the pulley surface shown in Fig. 12. To this must be added the pull required when the belt is leaving the pulley. A stamp may be easily placed on an envelope but some action is required in its removal. At your next opportunity notice a drive of this description and listen to the noise when starting or stopping. Just like pulling a porous plaster from your back.

However, where the excessive and needless use of belt dressing is more pronounced is on cone pulleys, where belts are required to be changed from one speed to another. The action of the latter is very similar to that of the straight pulley, but where the greatest trouble is caused is on the flange or shoulder. The accumulation of the dressing at this portion soon attracts the edges of the belt, with the result that it shows a marked tendency to climb to the next higher step, and very often succeeds, the inevitable consequence being a broken belt or lace, generally the latter. At other times the belt may climb, but instead of taking the next step will flop or twist completely over, once or perhaps twice. The writer has seen this happen on several occasions. These conditions should not be allowed to continue, and pulleys should be scraped clean as soon as possible. Even without the presence of dressing, belts on cone pulleys may often show an inclination to climb, due to faulty belt or pulley alignment. To assist in the proper running of the belt the flanges or shoulders should be undercut as shown in Fig. 13 at B. This provides a point of contact for the belt at C, the edge being kept clear of the flange throughout the entire wrap of the pulley.

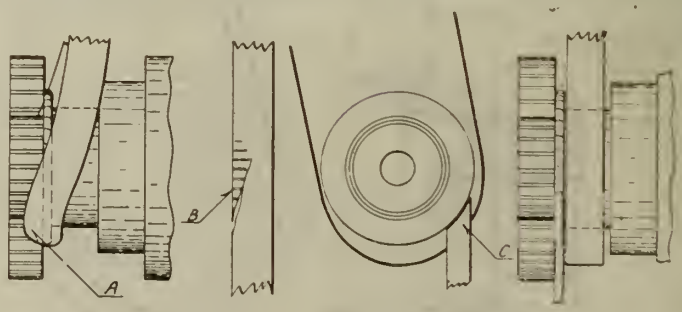

FIG. 16

Covering a Pulley With Leather

Many men resort to the practice of covering pulleys with leather to increase the adhesive power of the belt. When doing this the method generally adopted is to form an endless belt by means of splicing. First cut a piece of belting the required width to a length L, equal to

about ⅛ inch per foot less than the circumference of the pulley; connect the splice in the usual manner, and when set, place the ring over the pulley, starting it evenly all round. Coat both the inner surface of the belt and the outer face of the pulley with hot glue, then take the pulley up by the spokes and carefully work the leather ring into place by

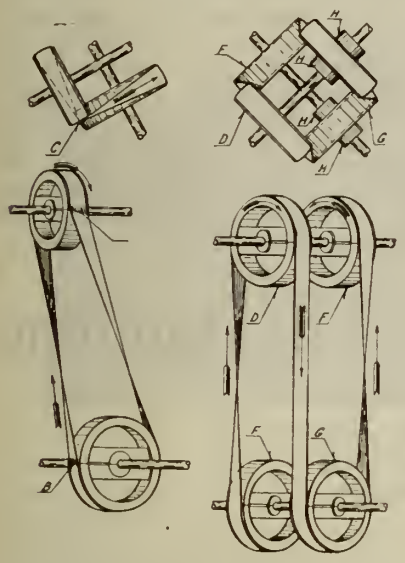

FIG. 17

bumping the edge on the floor or surface plate. Do this gradually to avoid kinking the leather, and quickly to prevent the glue from premature setting. If deemed advisable, a few copper rivets may be used.

Faulty Use of Nails

A leather-covered wooden pulley that came to the notice of the writer some few years ago was quite interesting and bears description. This pulley was located on the extreme end of a line shaft and was utilized to drive the countershaft of a buffing machine situated on the floor above. The buffer was subjected to very heavy service, frequently almost stopping at times, causing the belts to slip. Upon one occasion the writer was called upon to repair the main drive belt. Upon investigation it was found that the main drive was in a very dark storage room and the belt could only be seen by means of a special light taken to the ceiling. As stated, the pulley was found to be covered with leather, but a glance at the belt showed a strip right through the center on the inner side, that was in a deplorable state. Looking to the pulley for a cause it was discovered that the leather covering had been put on with nails, and several of these were protruding from ⅛ to ¼ of an inch. In this particular instance the nails were removed and replaced by fine wood screws, which proved successful. Probably the man that first covered this pulley thought that the belt would do its own driving.

Throwing Belts on Pulleys

A feature of factory operation that involves considerable risk to the workman, yet one that will likely never be discontinued, is that of throwing belts off and on the pulleys while the same are in motion. If shafting had to be stopped or even slowed down every time a belt required to be placed on or removed from a pulley, the suspension of production would be almost prohibitive, therefore the danger incidental to the maintenance of belts will always be with us. For this reason we should adopt the safest means of carrying out the work.

In the throwing off of a belt the risk is lessened by the fact that the belt comes off of its own accord in the greater number of cases, owing to slackness, poor alignment, broken lace, or one of many causes. When a belt requires to be thrown off a suitable stick is invariably used, but care must be exercised in its manipulation. Pressure should be applied at the leading side of the belt, that is, the side that is passing "on" to the pulley, and it should be seen that sufficient space is available at the side of the pulley to take the belt without it interfering with adjoining pulleys or couplings. If belts are thrown off regularly, other than for repairs, provision should be made to carry the weight of the belt so that it will not rest on the constantly-revolving shaft.

Proper Position of Ladder

When placing a belt on the pulleys it should first be located on the "dead" or driven pulley, as shown in Fig. 15, the actual running on of the belt being done on the driving pulley. As the latter is usually on the main shaft, in the majority of cases a ladder is necessary, and in placing the ladder, care should be taken to locate it on the outside of the drive, as shown at A. With the exception of special cases, where the drive shaft is located along a wall, the ladder should never be placed in the position B, and when such is absolutely necessary the shaft should be stopped and the belt run on at a very slow starting speed.

When standing on a ladder for this work the body should not be in a strained position, and one hand should be placed on a fixed object for support. For the lighter sizes of belts it is seldom that the speed of the driving shaft is reduced, as the knack is soon acquired of running the belt on. On the heavier belts the work is more difficult, but dexterity is attained with practice. When the belts are very heavy or extra tight, or with a load on the belt, "snapping on" is not so easy, and slipping of the belt is often necessary, while speed is accelerating. Under these conditions, however, care must be taken that the belt does not run off the driven pulley. On narrow pulleys there is always the possibility of the belt jumping off on the opposite side. Where possible, a good method is to place the ladder close to and on the opposite side, as at A, so that the lower edge bears against the pulley and acts as a guide for the belt.

Vertical Drives

If the belt is too tight or too heavy for the hand method, that shown at E may be adopted. By means of a light rope the belt is locked to the pulley and drawn on by slowly revolving the shaft. For vertical drives the same precautions are required. The correct method is that shown at C, where the belt is gathered up and placed on the far side of the pulley and drawn around to the near side, the ladder being placed as shown. A dangerous practice is that illustrated at D, where the belt is placed at the near side and followed on by the hand to the far side. This brings the arm in close proximity to the shaft at the final jerk of the belt as it takes the pulley, with the accompanying risk. When it is necessary to place the ladder in this position the workman should stand well up on the ladder, and it is also advisable to slow down the speed of the shaft. In the handling of belts, due consideration should be given to the surrounding conditions and at all times lean to the side of "Safety First."

Lathe Belt in Back Gear

A not uncommon occurrence in the operation of a lathe where the workman is not conversant with the proper knack, is that of the lathe drive belt jumping over the back cone flange and getting caught in the teeth of the gears, as indicated at A, Fig. 16. After this has happened the belt will have an appearance something like that at B. Where there is a danger of a belt running into gear trains, guards should be placed in suitable positions to protect the belt, as nothing will destroy a belt quicker than mangling it in the teeth of gears. For protecting a lathe belt a simple guard made of sheet steel, proves very efficient.

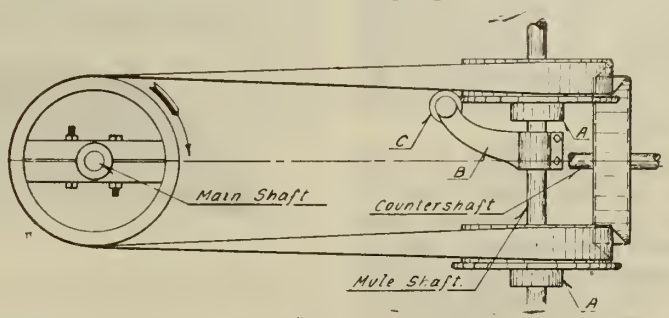

FIG. 18

Installing a Quarter Turn Drive

Drives other than those connecting parallel shafts are occasionally required, and local conditions must govern their installation, as a specific method is generally necessary for each individual installation. The most common is that of

the quarter turn drive, and it may be accomplished in a variety of ways. The simplest form is that illustrated at the left of Fig. 17, where the shafts are placed at right angles, with the pulleys properly lined. The fundamental requirements in a drive of this character is that the points A, B, where the belt leaves the pulley, will be on the same vertical line as indicated at C. This is essential, otherwise the belt will not remain on the pulleys without the use of guides. One great objection to the two-pulley quarter turn drive is the fibre stress resulting in the angle of the belt in leaving the pulley. This fault is less pronounced if the shaft centers are relatively far apart.

A better form of quarter turn drive, but one that requires four pulleys and about twice as much belt, is shown to the right of Fig. 17. In this case one of the pulleys on each shaft must necessarily be a loose pulley, running in the opposite direction to its mate and kept in alignment by the collars H. The unavoidable quarter twist is required in the belt, but the fibre strains are less pronounced. With this method the belt can be run in either direction, whereas that shown at the left can only be run in the direction indicated by the arrows.

The Mule Drive

Another drive that is occasionally used is that illustrated in Fig. 18. This is known as the mule drive and is adopted where a machine is to be operated at right angles to the line shaft and where a quarter turn drive is not permissible. In the mule drive the connected shafts usually lie in the same horizontal plane, invariably at right angles, where the prolongation of the counter shaft would intersect the main shaft. The intermediate pulleys revolve in a horizontal direction on a vertical shaft. When it is desired to run the belt in either direction it is advisable to have the two main pulleys of the same diameter. Collars are necessary on the vertical shaft to support the pulleys. One bad feature in a mule drive, where the load is a fluctuating one, is the tendency of the belt to run off the mule on the slack side. It is preferable to have the pull come in the lower side, but in either case the slack side should be provided with a guide pulley C, carried in a bracket B fixed to the mule shaft. This will aid in supporting the belt when the load is on the machine.

Power Plant Management; Coal and Ash Handling

PART III.

The Use of Continuous Belt Conveyors—Hoists—Hoist and Telpherage—Locomotive Cranes for Coal Handling—Skip Hoists—The Necessity for Adequate Capacity

By ROBT. JUNE

IN our preceding discussions we have considered the advantage of coal and ash-handling equipment from the standpoint of elimination of uncertain labor element, increase of coal storage capacity, and reduction of handling costs, and have called attention to the necessity for expert advice and detailed study in the selection of methods and equipment for any particular plant.

We have seen that the fundamental requirement of any proposed installation is that it shall satisfy the formula that O H I shall be less than H; that is, that the operating costs O, plus maintenance costs M, plus interest on money invested I, of the system, which it is planned to introduce, shall be less than the cost H, of doing the same work by hand, or by some other system. We have indicated that it was generally preferable, though not always necessary, to divorce the coal and ash handling on account of the destructive abrasive qualities of the ash.

Taking up the various type of equipment, we have considered spiral, flight and scraper conveyors, aprons and V-buckets, and pivoted overlapping dump buckets, finding that the latter, although the most expensive system to instal of any of the chain types, is generally regarded by power plant specialists, in both the operating and consulting fields, as the most economical for medium and large-sized boiler plants.

Leaving the chain group we now come to continuous belt conveyors.

Continuous Belt Conveyors

Here we have a type of equipment possessing the distinct advantage over any previously considered, of being driven from any point in its length. The importance of this feature will depend upon individual conditions, but it should never be overlooked in planning a system for an existing plant. Further notable advantages are the simplicity of drive—a motor with connecting belt to one of the pulleys, generally sufficing the almost unlimited capacity—the width of the belt depending only upon sufficient fibre stress in the materials of which it is composed, and the flexibility of the system. Conveyors 700 or 800 feet from centre to centre, and capable of handling 400 to 500 tons per hour, are in successful use. The angle of repose of the material is the only limiting factor to the inclinations at which belt conveyors may be operated.

Movable trippers are used when it is desired to discharge the load evenly along the entire length, as for instance in a continuous row of bins, while fixed trippers are employed where the load is to be discharged at certain and somewhat separated points. The movable trippers are made in two forms, "hand driven" and "automatic." In the former they are moved from point to point by means of a hand crank. The "automatic" tripper is propelled by the conveying belt through the medium of gearing. It reverses its direction automatically at either end of the run and travels back and forth, continuously

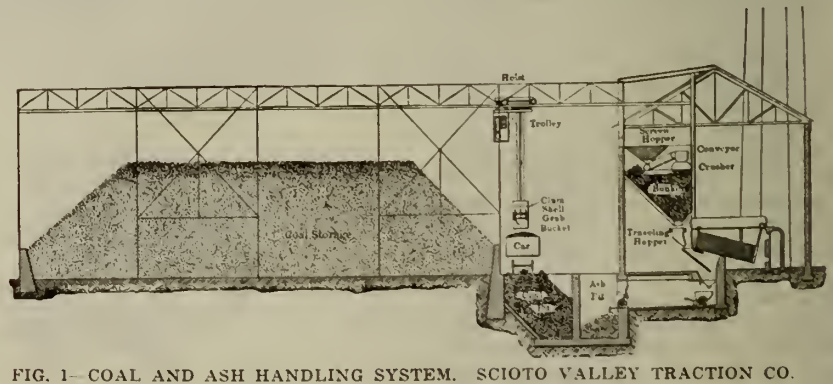

FIG. 1—COAL AND ASH HANDLING SYSTEM. SCIOTO VALLEY TRACTION CO.

In the Robins belt conveyor, which is typical of the best design and construction practice in this type, the material is discharged where needed by automatic tripping devices. The trippers consist essentially of two pulleys, one above and slightly ahead of the other, the belt running over the upper and under the lower one, the course of the belt resembling the letter S. The material is discharged into chutes on the first downward turn of the belt. The trippers may be movable or fixed, single or in series, distributing its load. It can be stopped, reversed, or made stationary at will.

As the material is actually carried it is possible to operate belt conveyors at much higher speeds than are possible with drags or any other types of carrying conveyors. The capacity of belts is therefore relatively much greater than those of other types of conveyors. It is the present writer's belief—a belief concurred in by many engineers, but not, be it noted by all—that belt conveyors should never, under any circumstances,

FIG. 2—SHEPHERD GRAB-BUCKET HOIST, POWER HOUSE, CITY OF HOLYOKE.

be used for the handling of ashes, for the following reasons:

1. High initial cost of installation.
2. Necessity for thoroughly quenching ashes before placing on conveyor to avoid destruction of belt by heat.
3. Rapid destruction of belt caused by abrasive nature of ash. There is an extremely good possibility of having to replace belts used for conveying ashes every six months, thus running the cost of maintenance up beyond all reason.

The power required to operate belt conveyors is stated by C. K. Baldwin in the following empirical formulas:

For level conveyors: $Hp = \frac{CTL}{1000}$

For inclined conveyors: $Hp = \frac{CTL}{1000} + \frac{TH}{1000}$

C equals constant as in Table I.
T " Load in tons (2,000 lbs.) per hour
L " Length of conveyors between centres.
H " Vertical life of material.

Belt conveyors may be regarded as better adapted to the requirements of large plants than to small.

Hoists

Of the various systems of hoists, such as hoist and hand car, hoist and cable car, and hoist and trolley, we can, in a general discussion, such as the present, dismiss the first two, since although there are several prominent installations of both types in the United States and Canada, the total number is comparatively limited, and it is apparent that these are types not likely to survive.

Hoist and Telepherage

The telepher is a type of hoist deservedly popular for small and medium-sized as well as large plants. In many ways the installation of the hoist and trolley systems appeals as one of the most logical and desirable solutions of the coal and ash-handling problem. It is, of course, used in connection with bucket or belt conveyors, as well as without. Where coal storage is desired and space adjacent to the boiler room is available, the hoist and trolley systems will generally prove the most economical installation, and the possibilities should be thoroughly canvassed.

Figure I, supplied through the courtesy of Professor Gebhart, shows the installation of a Jeffrey telepherage system at the plant of the Scioto Traction Company. With this arrangement, if the coal car is of the dump type the contents are discharged directly into the coal pit from which the coal is removed by grab bucket and transferred either to the overhead bunker or to the storage pile. If the coal car is of the gondola type the coal is removed directly from the car by the grab bucket. The bucket is hoisted and carried on the trolley into the building over the screen hoppers where it discharges its contents; the finer particles fall directly into the bunker and the larger lumps are automatically delivered to the crusher. The grab bucket will take about 98 per cent. of the coal in the car, leaving only 2 per cent. to be handled by hand. Coal is fed to the stokers by means of a traveling electric hopper which receives its supply from the overhead bunkers. The present capacity of the plant is 50 tons per hour taken from the car or pit to stock pile.

Where it is possible to use the telepher without employing some additional type of conveyor, notable economies in cost of handling can be effected. It would be hard to imagine a more effective or economical system for unloading coal from cars, storing it and supplying it to a battery of eight boilers than that illustrated in Figure II. An excellent feature of this system is that where the old boiler room is concerned, it can frequently be installed with fewer changes and at much less expense than would be possible with belt or bucket conveyors.

The hoist and trolley is one of the best forms of ash-handling equipment for use where ashes are produced in large quantities and are to be carried to a considerable distance from the plant. It is also an exceptionally good method for taking care of large, hard clinkers which cannot be broken small enough to be handled in other types of conveyors. For this reason it is particularly adapted to use with gas producers or other furnaces in which large clinkers and wet ashes are produced. In installing this class of equipment the trucks should be so arranged that the bucket can be dropped directly into the ash pit or directly in front of the ash door in hand-fired

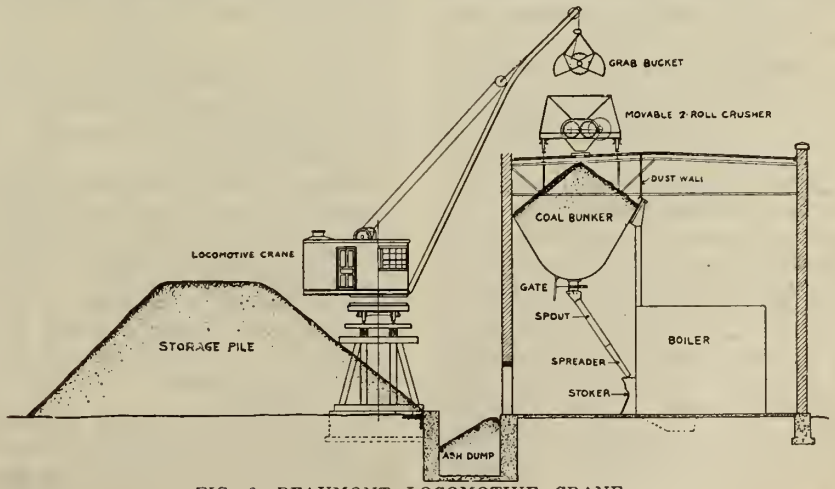

FIG. 3—BEAUMONT LOCOMOTIVE CRANE.

plants. The buckets should also be of sufficient capacity to remove the entire accumulation of ashes in one pit at one loading.

Locomotive Cranes

For small and medium-sized plants, where normal coal storage is desired, the locomotive crane is entitled to consideration. Figure III, supplied through the courtesy of the R. H. Beaumont

FIG. 4—BEAUMONT SKIP HOIST AND BUNKER, PHILADELPHIA SUBURBAN GAS AND ELECTRIC CO., PHOENIXVILLE, PA.

Company, shows a simple, effective layout for boiler room, with coal track and storage immediately adjacent. As between the locomotive crane and the hoist and trolley systems, local conditions and comparative costs of installation and operation, as worked out for the particular plant under consideration, will govern the choice.

Skip Hoists

As skip hoists are primarily ash conveyors we are brought, in discussing them, to a consideration of the desirability of divorcing the coal and ash-handling systems. As a general proposition this separation of the systems is emphatically desirable. Coal is, by nature, graphite and causes little wear to the conveyor. Ashes, however, are abrasive and may, in addition, be red hot or dripping wet. The abrasive quality produces excessive wear on chain conveyors. Red-hot ashes are practically certain to produce distortion and to some extent disintegration of the equipment.

A chain conveyor system which will handle both coal and ashes is expensive to instal, expensive to operate, and expensive to repair. The ashes get in the chain joints and therefore the system is subject to the abrasive action of the ashes even when handling coal. When handling ashes the entire apparatus must make a complete circuit in order to convey the ashes a short distance. Frictional losses are comparatively large for the work accomplished. Furthermore, in the usual installations no ashes can be removed when coal is being handled, or vice versa, and it is extremely likely that occasions will arise with considerable frequency when the equipment is urgently needed for both services at the same time.

If separation of the systems is a logical procedure the skip hoist is likewise a logical equipment for ash removal. The apparatus consists (see Figure IV) of a bucket running on inclined or vertical tracks and hoisted by means of a steel cable attached to a winding machine. The bucket consists merely of a rectangular steel box open at the top and fitted with guide and hoist bale.

The winding machine is usually driven by an electric motor.

The bucket is started upward by a pull on the starting rope or pushing a button. It discharges and returns automatically to the pit, where it stops. In some cases the skip reciprocates continually and is automatically filled.

The skip hoist is one of the best and most commonly used ash-hoisting devices. In connection with a small push or electric car to collect ashes from hoppers under the boilers it possesses the following advantages:

1. Durability: Ashes can be handled either wet or dry, hot or cold. The skip bucket is not materially affected by any of these conditions as are chain joints, elbows, exhausters, etc., constituting other types of ash-handling equipment. The hoist itself, being the only part that can be injured by the ashes, is always placed in a position remote from the skip so that dust or dirt cannot reach it.

2. Adequate capacity: A 35-cubic-foot trolley ash hopper car on 130-foot haul travelling 400 feet per minute, can make a round trip (260 feet) in two minutes including filling and dumping, assuming that ashes will flow by gravity into car. This equals twenty (20) tons per hour for the extreme haul, or forty (40) tons per hour for average haul. A skip, consisting of two buckets, one going up while the other is coming down, can make a trip in 90 seconds, including filling and dumping. If buckets are 35-cubic-feet capacity each the capacity would be 28 tons per hour at 50 cubic feet per ton and 50-ton lift. Plants producing large quantities of ashes are thus easily served.

3. The car and skip method is about the only successful method for handling extremely large and hard clinkers. The clinkers handled by this system need little breaking.

4. Power is used when ashes are being actually hoisted and is not wasted while ashes are being brought to the hoist.

5. The skip hoist can easily be designed and constructed so that it can be loaded or dumped at different levels. In this way it is possible to handle ashes from boilers on different levels in the same hoist, and also to discharge at different elevations.

The disadvantages of the skip hoist are comparatively high initial cost, so that the economical value of the installation is questionable where there is less, say, than 3,000 h.p. of boilers to serve. A further disadvantage is that the ashes must be moved from the boilers to the hoist by manual labor. The car and skip hoist system should never be considered for installation in a plant that is not provided with ash pits from which the ashes can be dumped directly into the cars, otherwise too much labor is required for loading the cars.

THICKNESS OF FIRES

The fire under a boiler should be kept as thin as practicable, in order to avoid the formation of unnecessarily large quantities of carbon monoxide gas. There is no loss from the production of this gas, if it is all burned again in the furnace; but when it is generated in great amounts, the escape of some sensible portion of it in the unconsumed form can hardly be avoided. Many persons believe that carbon monoxide is formed only when the fire is black on the top, from the addition of fresh coal. This is an error. The production of the monoxide is due mainly to excessive thickness of the bed of fuel on the grates, or to deficiency in the air supply; and it may be generated in large volumes from either of these causes, even when the fire is quite bright. So far as concerns loss by the wasteful production of carbon monoxide (as distinguished from the loss by direct distillation, noted above), the blackness of the fire on the top is objectionable mainly because there is then far more likelihood that the monoxide, when formed, will escape unburned. The air entering through the ash-pit combines with the coal in the lower layers of the fire and forms carbon dioxide, which escapes unchanged if the draft is good and the fuel-bed is not too thick. If there is an excessive thickness of fuel, however, or if the draft is poor so that the gases require too long a time to pass through the fire, a further chemical action occurs, the carbon dioxide taking up more carbon from the heated coal in the higher layers of the fire, and becoming thereby transformed into the monoxide—two volumes of the monoxide being formed, in this way, for each volume of the original dioxide. When the fires are at all thick, especial care should be taken to admit more air, so that the monoxide that is formed may have plenty of oxygen mingled with it to enable it to burn properly. As a rule, the fire should not be more than eight or nine inches thick when burning hard coal, but with soft coal the fuel-bed must be somewhat thicker. The fire should be thicker at the back end of the grate than at the front, because air draws up through the fuel more freely at the back end, if the thickness of the fire is everywhere the same. This condition is usually met by slightly inclining the grates, and keeping the upper surface of the fuel-bed level.

Factors Affecting Refrigerating Plant Engineering

In a Paper Read Before the American Society of Mechanical Engineers—The Author Gives Some Interesting Data Relating to the Efficiency of Refrigerating Plants

By VICTOR J. AZBE

THE cost of ice and of refrigeration is a composite figure of many different expenses coming under the heads of manufacturing, selling and general expenses. The cost of fuel is usually the largest item, and it may easily represent the difference between profit and loss.

During the last two years the cost of fuel per ton of ice has doubled, and many plants are now paying $1.50 to $2.00 per ton of ice for fuel alone. In spite of these conditions the majority of refrigerating plants are very wasteful of fuel as a result of improper design, run-down equipment or poor operation. While the possible savings are enormous and can usually be secured with little effort and slight expenditure, the necessity for improving equipment and operating conditions is not realized in the majority of plants.

It should be the aim to improve the economy of the plants from year to year by making necessary improvements to reduce costs of fuel and labor. Fuel cost, while most important, is not all-important, however, and there are ice plants having a very high fuel economy that are losing money. A high efficiency must be maintained generally in the design of the plant, in its load factor and in its labor and sales organization. There are far more plants making on the average, per year, 1.5 to 2.5 tons of ice per ton of fuel than plants making 5 tons, having simple non-condensing plants in mind.

In this paper the writer expresses himself frequently in terms of tons of ice per ton of 10,000 B.t.u. fuel, to equalize the value of the various fuels (semi-bituminous, bituminous, lignite, oil, etc.) since by a simple recalculation it places them on a common basis.

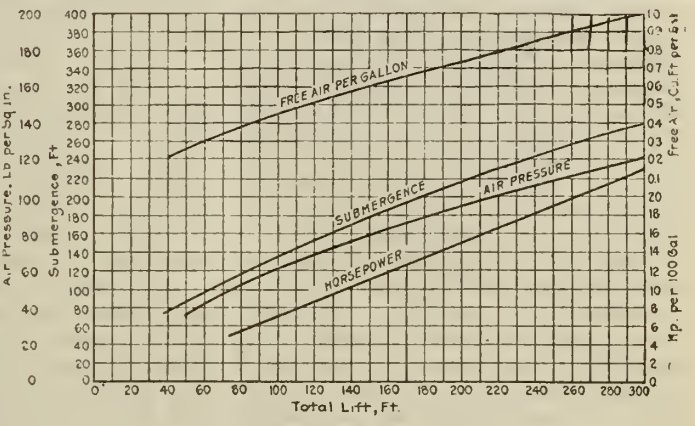

FIG. 2—STANDARD AIR LIFT PERFORMANCE

As the load factor of most refrigerating plants varies greatly, the boiler installation should be such as to give flexibility of operation. In small plants arrangements should be made to reduce the grate surface during the winter periods. Each boiler must be equipped with a draft gauge, and the draft should be maintained at the minimum and varied with the load. The boiler setting should be high, even with return tubular boilers, with a space of from 4 to 5 ft. between grate and boiler shell, and the combustion chamber should be so arranged that the benefit of this increased space is obtained. Gases tend to take the shortest path, and with most of the combustion chamber space devoid of drop walls there will be circulation of the gases and many eddy currents or dead spaces.

Any fuel can be burned if proper provisions are made—shavings as well as oil or semi-bituminous coal. The selection mostly depends upon cost and availablity. Lignite, for example, is a most excellent fuel for localities such as Texas. Burning this under return tubular boilers efficiencies were obtained of 63 to 68 per cent.

Prime Movers

The prime mover most generally used in refrigerating plants is the Corliss non-condensing steam engine. Next in order are the compound Corliss, electric motor, oil engine, and uniflow steam engine. If this order were reversed, however, enormous sums of money would be saved to ice manufacturers, for the following reasons:

In selecting the prime mover for an ice plant, the two most important items to consider are efficiency at rated load and efficiency at half load. While the average Corliss non-condensing engine consumes 20 per cent. more steam at half load than at full load, the uniflow engine uses only about 8 per cent. more. This is of great importance because of the great variations of load factor. Many engines can be found operating at one-eighth cut-off. This is the reason, also, why a steam cylinder should be adapted to the back pressure at which the compressor operates. It is most unwise to have a steam cylinder large enough for economical cut-off at 25 lb. suction pressure when the pressure to be maintained is 15 lb. or less.

Fig. 1 shows the results to be expected from various types of installations. The allowance made for auxiliaries ranges from one-half to one horsepower per ton of ice, depending upon conditions. The condenser pressure was taken at 185 lb. gauge, and it was assumed that at the suction pressure given the machine would operate at about full load.

In small plants preference should ordinarily be given to the use of superheated steam, since as high an economy may be obtained from a uniflow non-condensing engine operated with superheated steam as from a compound Corliss condensing engine using saturated steam, and the former equipment is a great deal simpler and necessitates less auxiliary power. Furthermore, the steam-consumption curve is flat and the efficiency of the plant will be maintained during the winter time.

FIG. 1—RELATIVE EFFICIENCY OF VARIOUS ICE PLANT INSTALLATIONS

Superheaters can be installed with facility even in existing installations, and since the gain is greater with simple non-condensing engines, uneconomical ice plants will derive great benefit from this procedure.

In order to gain in economy, a simple engine is often made to operate as a condensing engine. As a result, the temperature difference in the cylinder is increased and the cut-off is shortened, which increases the wall area at cut-off as compared to volume. This greatly increases cylinder condensation, which is directly proportional to the temperature difference and the area exposed. It therefore seldom pays to operate such a machine at more than 20 in. of vacuum, and if the plant is to be changed over to condensing operation, it is best to replace the simple Corliss by compound cylinders or by a uniflow engine and leave the rest of the machine intact.

Under proper conditions the ideal and most efficient prime mover for the ice manufacturer is the Diesel oil engine. By "proper conditions" is meant conditions of oil supply and cost, and kind of operating force to be employed. It cannot be over-emphasized that with the Diesel engine a high-grade engine-room force must be maintained, and especially during the overhaul period.

If the men in charge are intelligent, the Diesel engine is a very dependable unit. There is a plant in California that produces a ton of ice for 5 gal. of fuel oil, and this not under the best conditions. There are oil engine installations on record, not necessarily Diesel engines, that have given a ton of ice for less than 10 cents fuel cost, with oil at 2 cents a gallon.

With regard to the average results obtained with Diesel engines over a long period, the net work produced was 1,119,801 kw-hr. The auxiliary power represented the power required for injection in the air compressor, and in the water-jacket circulating pumps. The load factor having been highly variable, the results are not quite as good as they otherwise would have been, consequently the figures may be taken as being conservative and dependable.

Velocity of Brine, Ft. per Min.
DOUBLE PIPE AMMONIA CONDENSER
DOUBLE PIPE BRINE COOLER

FIG. 3 HEAT TRANSMISSION WITH DOUBLE PIPE BRINE COOLERS AND AMMONIA CONDENSERS.

In many localities electric power can be obtained cheaply, and when this is the case electric drive is to be favored. The main advantage of an electric installation is that high efficiency can be obtained through the whole load-factor range and that economy increases as the load factor drops, contrary to the condition in ice plants.

Induction motors are not very well adapted for ice-plant work because of the high speeds required for high efficiencies. Synchronous motors, on the other hand, have characteristics that make them ideal, even for direct connection to refrigerating machines. Their efficiency curve is quite flat and their efficiency is rather high at part loads.

An electrically driven raw-water plant is a great deal simpler than a steam-driven plant. Many factors which influence plant efficiency are eliminated, and consequently the operating man does not have to be as high grade as for the efficient operation of steam plants. Labor cost and repair expenses and the cost of real estate, buildings and machinery are all less. Dependability is also fair, and with proper installation as good as in the case of a steam plant.

Auxiliaries

The curse of most ice plants is the auxiliaries. In many cases the steam consumption of the auxiliaries is as great as that of the engine running the compressor. In a certain ice plant of 100 tons capacity the following auxiliaries were found in operation: Electric-light engine; duplex circulating pump for ammonia condenser; duplex circulating pump for steam condenser; duplex brine pump; duplex boiler-feed pump; ice-hoisting compressor; single-stage single-steam-cylinder deep-well compressor; agitator engine and cooling-tower fan engine.

One of the most uneconomical auxiliaries as usually operated is the air lift. This statement is meant as no reflection upon the air-lift pump as such, but on the way in which it is usually operated. Fig. 2 shows the performance of properly designed air lifts; the efficiency decreases somewhat as the lift increases, but should not be less than 60 to 80 per cent., whereas, actually in some cases it will be found as low as 20 per cent.; the trouble is usually too great or too little submergence.

It is seldom advisable to use an air-lift pumping system for the circulation of water over the steam condenser because of the increased head required. The use of a cooling tower is ordinarily to be preferred, and any water needed for make-up may be taken from the air-lift system and passed over the distilled-water and liquid-ammonia coils, thus cooling the latter below the temperature of the circulating water proper.

For driving auxiliaries, electric current from generators driven by uniflow engines is to be preferred in the majority of installations, and the various units must be selected with a view to obtaining a flat efficiency curve between

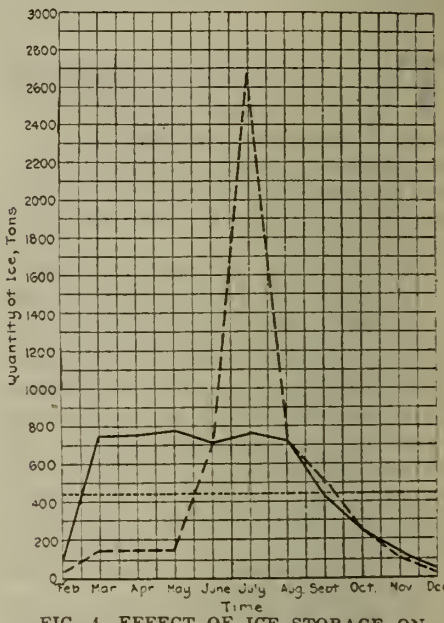

FIG. 4—EFFECT OF ICE STORAGE ON EXTREME LOAD FACTOR.

half and full loads; all motors on the larger units should have variable speed control. Duplex steam pumps or steam-driven deep-well pumps should not be used except possibly as a reserve.

Wet Versus Dry Compression

Theoretically, dry compression is inferior to wet, both in regard to refrigeration produced per pound of ammonia circulated and the work required for compression. The difference in economy ranges between 6 and 10 per cent.. being greater with low suction pressures and high condenser pressures. Practically, however, dry compression is the more economical; that is, it is capable of producing a greater amount of refrigeration per horsepower expended. The reason for this discrepancy is that when wet gas is admitted into the cylinder the liquid is not suspended, but accumulates at the bottom of the cylinder. There it evaporates so slowly during the compression stroke that the evaporation continues after the discharge valve opens, and often even after it again closes when the piston is upon the return stroke, thus causing a certain amount of re-expansion loss which tends to reduce compressor capacity. Any liquid that evaporates after the discharge valve opens is utterly wasted.

That there is no benefit in wet compression, as ordinarily practised, is proven by the compression curve and its relation to the adiabatic and isothermal curves when the machine is operated wet, even to such an extent that the discharge gas leaving the compressor is saturated. In such cases the compression curve will only slightly approach the isothermal, which proves that most

of the cooling of the gas by evaporation of the liquid is done after the compression valve opens and thus no benefit accrues from that time on. Liquid and vapor flow separated within the same pipe the same as in the case of saturated steam.

So long as theory indicates an advantage in wet compression, it would seem that further studies and experiments regarding its successful application are justified. Could not some

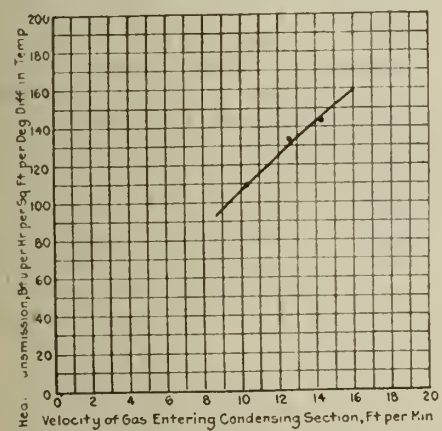

FIG. 5 EFFECT OF VELOCITY ON HEAT TRANSMISSION

method be devised to atomize the liquid before it reaches the compressing cylinder, or to inject it in the form of a spray during the compression stroke? In any event, precautions must be taken not to introduce liquid into the cylinder in an undivided state, otherwise dangerous accidents are likely to follow.

Wet compression is not only beneficial upon thermodynamic principles, but possesses a number of other advantages. By its use the temperature difference in the cylinder is reduced by practically two-thirds, which greatly lowers the cylinder superheat and consequently should increase the volumetric efficiency of the machine. Further, with wet compression far less oil is required for lubrication, and the oil does not vaporize, and thus is easily kept out of the condensing and evaporating coils. Wet compression represents also a saving in ammonia and, in addition, permits a somewhat lower condenser pressure.

Ice Tanks

All the details incidental to the process of ice making should be so regulated as to secure a high rate of heat transmission, coupled with a low temperature difference. The ice tank is a most important member of the ice plant. As far as handling is concerned, great improvement can be made. In a certain plant in St. Louis it was arranged to hoist a row of eighteen 200-lb. blocks by one operation, and the blocks were all thawed and dumped at the same time.

Circulation of the brine in the freezing tank is a very important item. This circulation is at times produced by centrifugal pumps, but ordinarily by propeller agitators. Often these agitators are very inefficient and tend more to churn the brine than to circulate it. It is ordinarily difficult to determine what the circulation in an ice tak, is due to the fact that the speed of the brine varies and its velocity in the lower part of the tank is not the same as in the upper part. About the most practical way is to measure the difference in the height of the brine in the tank on the suction and discharge sides of the bulkhead close to the agitator. With tanks as ordinarily constructed, 1 in. difference of level for each 10 cans of tank length is assumed by the writer as a standard. This method should be fairly accurate since brine flow is the result of difference in level.

In agitating the brine, its level should never be below the level of the water in the can. Too low a brine level will greatly reduce the capacity of the tank and also the plant efficiency. A wide, shallow hole in the top of the clock toward the end of the freezing period is always an indication that the can is too full or the brine too low.

Since with long tanks or very strong agitation, considerable brine levels difference is produced, in some cases as much as 5 in., it is best to construct long ice tanks with agitators on each end. Brine velocity is helpful in two ways; it increases heat transmission between the brine and the can, and between the evaporating coil and the brine.

The average transmission of heat from the ice in the can to the brine outside is very poor, only about 2.5 B.t.u. per deg. per hr. per sq. ft., due to the insulating effect of the ice. The thicker the ice, the slower the heat exchange, consequently tank brine velocity has not nearly so great an effect upon heat transmission on the can side as it has on the coil side. The heat transmission between ammonia and brine through metal is between 10 to 20 B.t.u. per sq. ft. per hr. per deg. This comparatively low figure is primarily due to the superheating of the gas in the coil, which causes one side of the surface to be dry, and secondly, to the low brine velocity.

Fig. 3 gives York Mfg. Co. curves showing heat transmission with double-pipe brine coolers and ammonia condensers. The curves were extended by dotted lines to show probable transmission at low velocity. These curves from their characteristics show the importance of velocity, an item which from the economy standpoint is certainly worthy of careful investigation.

Ammonia Evaporating Systems

With expansion coils in ice tanks and cold-storage rooms a high heat transmission is very desirable, and it can be obtained inside of the pipes either by flooding or using a high gas velocity. The objection to high gas velocity in this connection is pressure drop, which for thermodynamic reasons is rather more important on the evaporating side than on the condensing side. For this reason, the length of the evaporating coil should be limited so that the velocity will never exceed the average figure of 500 ft. per min. Some tank coils are 1,500 ft. long and their rather high velocity causes a great pressure drop. For long tanks 2-in. pipe is to be preferred, since the relative surface of 1¼-in. and 2-in. pipe is in the ratio of 1 to 1-5, while the sectional area is in the ratio of 1 to 2.2. Coils should be short so that they are thoroughly effective, and even flooded coils should be as short as possible. The size of suction lines leading to the machines should be governed by permissible gas velocity, friction, and radiation loss.

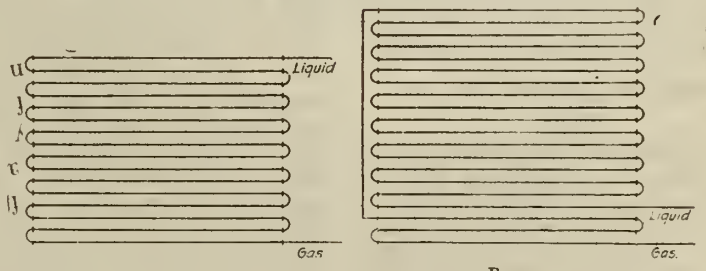
Ice Plant Load Factor—Ice Storage

Ice storage is profitable in most cases if the storehouse is filled to capacity during the winter and emptied entirely in the summer. The cost of storehouse will be from $6 to $12 per ton capacity and the investment will net a substantial return in most cases. The objections to it are the cost of refrigeration for the storage and the increased cost of handling the ice.

As far as plant economy goes, the value of ice storage is due to the equalization of the load factor. That is, the plant can be operated at higher rate during slack seasons and there may not be the necessity for forcing the plant beyond its economical limit in summer. The ice plant and ice storage can be so proportioned that the plant will have a load factor of 80 to 90 per cent., while without ice storage it would be only about 40 per cent., taking the whole year into consideration.

The small ice vault, or daily ice storage, exerts also quite an influence upon plant economy and it cannot be overemphasized that it is advantageous to make it amply large. The idea is to remove ice from tanks as quickly as possible—to use ice tanks for storing ice is a very poor practice.

In Fig. 4 the full line represents the output of ice; the broken line indicates the sale of ice, and the dotted line the proper rate of manufacturing ice. These curves were plotted from the figures



B

FIG. 6—AMMONIA CONDENSER TYPES.

actually obtained in a plant. An exact determination of the proper rate of manufacturing ice will permit stopping the plant altogether for a certain time and attending to repairs.

To operate with low suction pressure is far less economical than is indicated by the analysis of compressor performance alone, for the reason that the economy of the engine is also affected by the reduction of the load. For this reason, when the condenser pressure drops off during the cold season it is doubly important that the suction pressure be increased and the machine maintained fully loaded. The practice of

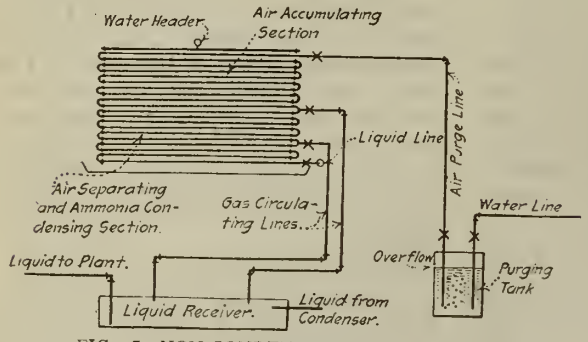


FIG. 7—NON-CONDENSABLE GAS PURGING ARRANGEMENT.

shutting down one or more ice tanks in winter should be strongly condemned, and no tank should be shut off (except in case of absolute necessity) until the back pressure is at the highest point. Efforts should be made to maintain a back pressure of 30 lb. in winter and the plant should be designed with that in view. The largest loss is occasioned by the non-adjustment of the various elements to the load factor.

The various rooms or tanks in an ice plant should either be maintained at the same temperature or designed especially for low temperatures. To try to maintain one or two rooms at a low temperature and sacrifice the economy of the whole plant is bad practice, since the suction pressure will always correspond to the lowest temperature. The temperatures should be maintained uniform. When this is not possible, and the difference in the various temperatures is great, then either a multiple effect or a booster compressor should be installed.

Forecoolers and Multiple-Effect Receiver

In a well-designed and efficiently operated ice plant the water to be used for ice making is cooled down to within a few degrees of the coldest circulating water, or ordinarily to a temperature of 70 or 80 deg. Fahr. This water then passes into the forecooler to be precooled by ammonia. The heat absorbed by the forecooler can be anywhere up to 30 per cent. of the total heat to be extracted in making ice, and the water will be cooled down to about 40 deg. Fahr. There are two methods of forecooler refrigeration: by feeding liquid ammonia directly into a coil, or by passing wet return gas from the tank through the water cooler. The first has the advantage that it can be connected to a machine working independently from the freezing tank and thus enable the maintenance of very high suction pressure. The only advantage of passing the suction line through the forecooler is that the expansion valves on the tank can be kept open wider, thus insuring that the freezing coils will work throughout their whole length without danger of getting any liquid to the machine. But this same thing can be accomplished far better by means of liquid separators and it is of greater advantage to use the high suction pressure which is possible with direct feeding.

Refrigerating plants should also be equipped with double-pipe liquid pre-coolers, cooling the liquid from the temperature of the coldest circulating water down to the temperature corresponding to the highest suction pressure used. In this connection a multiple-effect liquid receiver can also be used, by means of which a greater amount of work can be done at high suction pressure than by the use of the double-pipe cooler alone.

Every refrigerating plant should have an auxiliary compressor for high-pressure work. The size of this compressor may be relatively small for the reason that it will operate at double its rated capacity. One of the most valuable inventions ever made in the refrigerating field is the multiple-effect compressor, which allows gas of higher suction pressure to enter the cylinder after it has been filled with gas of a lower pressure.

Ammonia Condenser

There is no reason for a condenser pressure as high as 200 lb. It always indicates improper conditions, and even in a hot climate the condenser pressure should be below 175 lb.

The cooling tower should cool the water within three degrees of the wet bulb. The relative positions of the condenser and cooling tower should be such that five to six gallons of water can be pumped economically; that is, the pressure due to the head should be less than 15 lb. The condenser should give a heat transmission of at least 150 B.t.u. per sq. ft. per hr. per deg. There should also be sufficient surface, and if the condenser gives better results, less than the specified surface will be needed. In actual practice, results ordinarily are far inferior, due to the water being too warm, to the lack of a sufficient amount of water or of the required condensing surface, to the use of a poor type of condenser, or to the presence of oil or air in the condenser or scale on the outside.

The condenser should be located on the roof of the building, with the cooling tower immediately underneath and so placed that the coils will be parallel with the prevailing direction of the wind in the summer.

The cooling of the water over the condensers is important, not only because it simplifies the action of the cooling tower, but also because it produces a greater temperature difference between the water and the ammonia and thus lowers the condenser pressure. Theoretically the ideal arrangement would be for the initial and final temperatures of the water to be the same. This is often realized in winter and is also quite possible in summer in a dry climate with good wind velocity and sufficient condenser surface. It is important to protect atmospheric condensers from the sun

Condensing coils give a much greater heat transmission per degree difference in temperature than evaporating coils. Better results are obtained with the double-pipe condenser than with the atmospheric because of the higher water velocity of the former. Taking into account the question of initial cost, however, an atmospheric condenser, well exposed, should give, for the same expenditure, as good results as the double-pipe condenser.

TABLE 2—AMMONIA CONDENSER PERFORMANCE

Table 2 gives the results obtained from tests performed upon condenser sets in actual operation. Type A was a counter-current flooded atmospheric con-

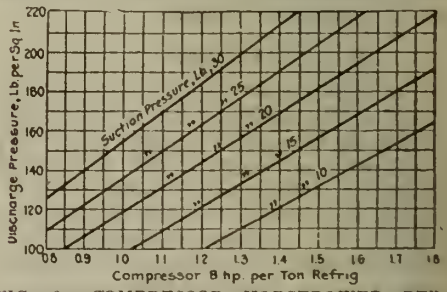

FIG. 8 COMPRESSOR HORSEPOWER PER TON REFRIGERATION.

denser. Type B was a condenser installation consisting of ordinary atmospheric condensers with three superheat pipes at the bottom of each stand. The result in tests 2 and 3 were obtained with type B. When test 2 was conducted the condenser surface was very clean both inside and outside and the

condenser was free from any non-condensable gases; this probably accounts for the favorable performance secured. The value in test 3 fairly agree with the ordinary performance of condensers similar to B. The writer possesses data of tests performed upon a dozen of these installations, which show practically the same figures.

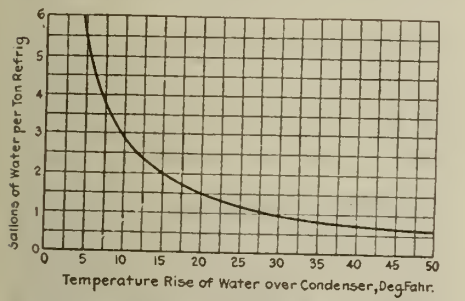

FIG. 9 — TEMPERATURE RISE OF WATER OVER CONDENSER WITH VARIOUS AMOUNTS OF WATER AND NO ATMOSPHERIC COOLING.

Fig. 5 presents the effect on the transmission of heat of the velocity of the water in the pipes of a condenser. The points in the graphs were plotted from values obtained with a 12-pipe condenser of the drip-pipe type.

The velocity of the water in the pipes of a double-pipe condenser may be increased by allowing a greater amount of water to flow through them. The gas velocity increases when the height of the stand is increased by the addition of more pipes. In selecting between high and low condensers, however, other factors must be considered in addition to the water or gas velocity. Generally speaking, high condensers are preferable when the available water is cold.

When a condenser is operated with superheated gas, this should not enter at the top of the stand, as is often done in practice. Type B in Fig. 6 is a convenient form of a condenser for use with superheated gas.

A rather frequent objectionable condition is the presence of air in the condenser. In order to be able to extract without interfering with the operation of the remainder of the system or losing much ammonia, the condenser must be provided with a suitable purging arrangement, as, for example, the one represented in Fig. 7, which was used with installation B, in test 2, table 2.

The presence of air in the condenser often causes the cessation of the flow of the liquid through the pipes and thus seriously impairs the efficient performance of the condenser. The author has had occasion to observe in certain plants he inspected that the condenser pressure dropped 20 to 30 lh. after the air was removed from the system.

Fig. 8 shows distinctly how the compressor horsepower per ton of refrigeration increases with the rising condenser pressure, and decreases with rising suction pressure.

Fig. 9 shows how the consumption of condenser water per minute per ton of refrigeration increases as its temperature range over the condenser is decreased, it being assumed that for each ton 350,000 B.t.u. must be removed per 24 hours, inclusive of the heat equivalent of the compressor horsepower.

Cooling Towers and Spray Systems

The economy of a refrigerating plant depends largely upon the temperature of the water circulated in the condenser. Water for ammonia-condensing purposes can be obtained from deep or surface wells, flowing streams or city distribution systems; or by recirculating water that is being cooled in forced-draft, natural-draft or atmospheric cooling towers or spray cooling systems. Which method is to be preferred depends upon the temperature of the water, the dependability of the supply and the relative pumping level. The cost of pumping water from wells is ordinarily so great that a recooling system is preferred.

The proper construction of a cooling tower is far more important in a refrigerating plant than in a steam plant. In the latter we can get 25 in. of vacuum with water at 105 deg. Fahr.; but in the refrigerating plant, with the same temperature, the ammonia condenser pressure would be about 280 lb.

The limit of atmospheric cooling depends upon the wet-bulb temperature. The rate of cooling depends upon the vapor-pressure difference between the dewpoint and the temperature of the cooling water as modified by the wet-bulb depression. Roughly speaking, each degree of water temperature is equivalent to three pounds of condenser pressure.

The use of a properly designed cooling tower is preferable to pumping water from a well, except when the well water is very cold. In summer, in even the hottest and most humid parts of the United States, the temperature of the water in the cooling tower will hardly ever be 85 deg. Fahr.; it will ordinarily be below 80 deg. Fahr. an din winter 50 deg. Fahr. and even less. In fact, with a cooling tower it is not impossible to obtain in winter a condenser pressure of of 65 lb., while with well water, the temperature of which keeps more uniform throughout the year, the pressure is higher in winter. The towers should not be built square but rectangular, twice as long as they are wide, and should be placed so that the wind strikes on the lower side.

The proper relative position of the cooling tower, as regards the condenser, is a most important feature. It must be remembered that the auxiliary power should be kept down to the minimum of ½ h.p. per ton of ice, also that if the head is reduced more water can be pumped with the same power and thus lower condenser pressures are obtained. In many plants the cooling tower and condenser are placed on the same level with the result that two circulating pumps are operated in place of one. The relative position of the cooling tower and the condenser should always be one above the other, with the preference of the condenser being in the higher position, since unobstructed air access is more important with an atmospheric condenser than with a cooling tower. Both are more conveniently located upon a roof.

The spray system has recently been introduced in connection with ammonia condensing systems and very good results are being obtained. Its cooling efficiency varies from 45 to 70 per cent., depending upon humidity, wind velocity, fineness of spray and pressure at the nozzles. In the calculations which must be made for designing a spray system, however, it is advisable to figure its operating efficiency at 50 per cent. This value has been assumed in the preparation of the curves in Fig. 10, which show the value of the temperature of the water before spraying and the corresponding values after spraying, for various wet-bulb temperatures.

The advantage resulting from the use of a spray system in an ammonia condensing installation is that it reduces the power required, because a spray system does not involve the action of a fan, and a pressure at the nozzle of only six or seven pounds, that is, the equivalent of a lower 14 ft. high is sufficient. Also, the cost of construction and maintenance is less for a spray system than for a cooling tower.

FIG. 10—PERFORMANCE OF SPRAY SYSTEM

Distille dand Raw Water Systems

The advisability of using water evaporators should be carefully considered before adopting a raw-water system in a steam plant. Where the quantity of the available water is such that raw-water ice cannot be made successfully, the installation of evaporators is highly desirable.

There are two types of evaporators, high-pressure and vacuum. Under proper conditions both give satisfactory service and neither one develops as much trouble from the formation of scale as is ordinarily assumed. The writer knows of evaporators operated successfully in a region where the water contains a large amount of salt, a large amount of carbonates, and considerable calcium and magnesium sulphate.

The Oxide Film Lightning Arrester

A Recent Development in the Protection of Electrical Apparatus From the Effects of Lightning. An Interesting Principle is Involved

THIS article gives a brief summary of the scientific principles underlying a new type of lightning arrester called the "oxide film arrester." The functioning of this arrester depends upon the fact that certain dry chemical compounds can be changed with extreme rapidity from very good conductors of electricity to almost perfect non-conductors by the application of a slight degree of heat. Lead peroxide is a good example of such a substance. It has a specific resistance of the order of one ohm per inch cube. The resistance varies with the pressure to which it has been compressed. At a temperature of about 150 deg. cent. the lead peroxide (PbO_2) will be reduced to red lead, commercially known as minium (Pb_3O_4). This has a specific resistance of about 24 millions ohms per inch cube. At slightly higher temperatures this minium will be reduced through the sesquioxide (Pb_2O_3) to litharge (PbO), which last named is practically an insulator. [A megger reading of infinity is obtained on a column 3 millimeters long (0.11 in.) and 5 square millimeters area (0.2 sq. in.)]

Again the oxides of bismuth give similar characteristics. There are, furthermore, several other compounds

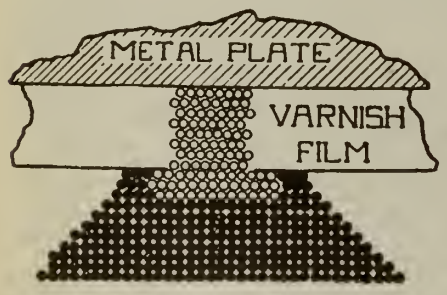

FIG. 2—DIAGRAMMATIC REPRESENTATION OF FILM ACTION.

and mixtures of compounds that will give these same results.

Lead peroxide is normally in the physical state of a powder. If this powder be placed between two electrodes and a current passed, the temperature due to the resistance at the contact of the peroxide and the metal will cause heat to be generated locally at the surface. When this heat is sufficient to create a temperature of about 150 deg. cent. a film of the lower oxides of lead forms, producing a film of insulation which stops the current. This method of film formation over any large area is rather irregular, and, of course, the oxide is not used in such a fashion in the commercial arrester. Instead of this formation of litharge film any insulating film may be put on the electrodes initially. As insulating film spread on the metal plates there have been used thin layers of the following: glass, water glass, halowax, cloth, balsam, shellac, oil, paints, lead paints, varnishes, and lacquers of all available kinds. In all cases the results are similar, varying only with the voltage at which puncture of the film of insulation occurs.

The foregoing statements define the principle of the commercial oxide film arrester. It comprises two sheet metal electrodes set about 0.5 in. apart, one or both covered with a thin insulating film and the space between the plates filled with some such substance as that described above as, for example, lead peroxide. At a permissible voltage of 300 volts per cell the insulating film prevents any appreciable current flowing under normal conditions. As soon as the voltage rises slightly above normal the film punctures in one or more microscopic points, the lightning charge meets with practically no resistance and flows to earth, Fig. 1. The dynamic current starts to follow, but because of the fact that the insulation was punctured in such fine points, the current density near these points is exceedingly great. This results in a localized heating which speedily raises the temperature to a value sufficient to change to insulating litharge all the conducting peroxide in this minute path of the current flow in contact with the electrodes. The film consequently reseals, stopping the further flow of dynamic current. This action is so rapid that its duration cannot be measured on an oscillograph giving two thousand cycles per second, that is to say, the action of resealing occurs in less than one four-thousandth part of a second after the excess of lightning voltage has ceased.

Fig. 2 shows a magnified, imaginary representation of one of the films on one metal plate. As shown, the film is punctured by a spark and filled with a litharge plug which is represented by the open circles. The cross-section in the discharge path, a short distance away from the metal electrode, is sufficiently expanded to make the current of low enough density not to heat the peroxide to a temperature of reduction to litharge. The peroxide is represented by the solid dots and only those in the path of the discharge are shown. At the other electrode, not shown in this magnified diagram, a similar effect may be taking place, although there is a difference between the positive and negative crators.

This film can be made of litharge itself, as well as any of the insulating materials above named. For example, metal plates may be inserted in any of the well-known lead electroplating solutions, and thus a very thin lead peroxide film (measuring a few hundred thousandths of an inch) formed. By proper

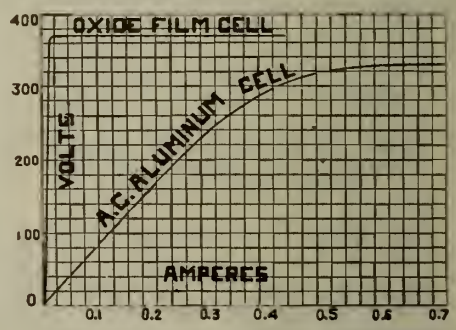

FIG. 1—CHARACTERISTICS OF ARRESTER.

heating this will be changed to litharge and this form of electrode can be used. Peroxide may also be sprinkled over any metal plate and the plate heated, which will reduce the peroxide to litharge. Again, the metal chosen for the electrode itself may be lead and if heated in the air a thin film of litharge will be formed on the surface. Again, an aluminum electrode may be put in any of the common electrolytes, and a thin aluminum film be built up. This may be used with the peroxide powder. Of these methods of forming the film the most preferable is by dipping in varnish or lacquer highly burnished surfaces of brass, steel, or copper, and is consequently used in the commercial arrester. The ohmic resistance of the arrester during discharge is quite low (less than 1 ohm per cell). Thus, when the insulating film is punctured the arrester offers very slight impedance to the flow of energy at abnormal voltages.

There is a certain range of voltage necessary to pierce any given insulation. The exact voltage depends not only upon the thickness of the insulation and its dielectric strength, but also on the relation of the dielectric spark lag to the duration of the super-spark potential and the frequency of alterations of the transient surge.

If an arrester is to give protection of insulation in shunt with it, the arrester must relieve the abnormal electric pressure before damage is done to the insulation. Although tests are frequently made with the arrester and the insulation it is to protect in parallel, a more convenient method has been standardized and is known as the equivalent sphere gap test. Both the insulation and the arrester are compared by comparing each to the equivalent sphere gap.

The equivalent sphere gap of the oxide film arrester may be analyzed, as in other cases, into separate and distinct parts. First, there is the equivalent sphere gap of the main gap to initiate a discharge through the insulating film on the plate surface of the cell. Third, there is the equivalent sphere gap of the resistance drop of the current discharging through the powdered peroxide in its path. Fourth, there is the equivalent sphere gap of the inductance of the arrester.

Commenting on these factors in their relation to this arrester, the main gap is itself a sphere gap which has the fastest spark of any practical gap. The gap setting, like that of the aluminum arrester, is only slightly above that of the normal voltage of the circuit.

The equivalent sphere gap of the film is several times greater than the thickness of the film because solid material has a greater dielectric spark lag than air, but with this multiple of the thickness of the film the equivalent sphere gap is still low. Since peroxide is a good conductor, the series resistance in the path of the discharge is insufficient to give an undesirable voltage drop. As to the inductance of the arrester, it has a minimum value due to the fact that each cell is only 0.5 in. long, and these cells are placed one on top of another. In other words, the total length of the arrester (which constitutes the inductance) is short as compared to the necessary length of conductor from line to earth.

One of the obstacles that had to be overcome in the making of this arrester was the increase in the resistance after a great many heavy discharges had passed through it. The predominant reason for the increase seems to be explained by the following theory: The current passing through this small puncture in the film heats up very rapidly not only the powder but also the air contained within the interstices of the powder. The particles are thereby thrown out of contact with each other, thus producing a fluffiness. The decrease in the number of contacts decreases the actual cross sectional area of conduction and hence increases the resistance. This raises the equivalent sphere gap. This action is accelerated, of course, by the giving off of the oxygen itself evolved in the reduction from lead peroxide to the lower oxide. If, however, this same arrester be violently jarred or the filling powder be compressed, or any other method utilized to restore the particles to their previous intimate contact, the equivalent needle gap will fall again. While increased fluffiness appears to be the predominant cause of change of the equivalent sphere gap, the increased thickness of the film of litharge at the point of puncture of the film is finally a factor of moment. The total area of the film must be sufficient to give a reasonable number of years of life to the arrester. There are other factors relating to the details of manufacture which give a limited degree of control over this change in equivalent sphere gap.

In all the commercial oxide film arresters used for alternating current the power factor is nearly unity. For special purposes, however, the power factor can be made anything desired from 10 per cent. to unity. This is obtained by combining with the conducting oxide other non-conducting materials. This principle has been made use of for condensers but it has not been found desirable to incorporate it in the arrester.

To summarize—an arrester operating under a new principle has been made which comprises in essence one or more metal electrodes covered with an insulating film, and separated by a conducting powder, which has the peculiar characteristic of becoming a non-conducting powder upon the application of heat. Voltage higher than that which can be withstood by the insulating film punctures it in one or more points of about 0.005 cm. diameter. Dynamic current flowing gives a high current density in the conducting powder adjacent to these punctures which in turn heats it up rapidly, reducing the powder to a non-conductor, and sealing the holes in the film. The powder being a poor heat conductor localizes this action, so that very little more powder is reduced than is actually necessary to seal up these minute punctures.

The critical spark voltage and that part of the equivalent sphere gap controlled thereby is a function of the thickness and kind of material used for the film.

Comparison of the "Oxide Film" With Aluminum Arrester

The earliest form of non-electrolytic film arrester was known as the dry aluminum arrester. It was a direct attempt to utilize the dry film which forms on the surfaces of pure aluminum immediately after it comes in contact with the oxygen of the air. The hydroxide film is easily formed in electrolyte and on drying becomes a dry film which gives sufficient action to prevent a discharge up to a given critical voltage, depending upon the thickness of the film. The film can also be formed by a spark or arc of a conductor in contact with a plate. Naturally this conductor should be of a non-metallic nature. In the earliest form tried powdered carbon was used mixed with dioxide of manganese which gives a liberal supply of oxygen at the heated point.

One of the objects of the development of this arrester was to decrease the cost of manufacture and it was found with the new principle involved in the oxide film arrester, where the powder furnishes the film rather than the plate, that the aluminum could be replaced by a cheaper metal, such as steel, and, as already described, the initial film known in the early stages of development as the "paint skin" type could be furnished by a layer of varnish. On first sight, knowing the extreme thinness of the hydroxide film on wet aluminum cell it might not seem that the dry cell would give the same general characteristics as the wet cell. But a comparison of the volt-ampere curves shows the same general characteristics. For a. c. voltages of 300 volts average per cell the current in the dry cell is of negligibly small value up to 40 milliamperes. The power-factor is nearly unity and the current flow is due to very slight leakages through the films. In the case of the aluminum electrolytic cells there is an equivalent condition, the d. c. leakage current of the order of one milliampere being due to leaks through the hydroroxide film. In the a. c. aluminum arrester the leakage current on the plate area used is much greater, due to the destructive action of the alternating current on the hydroxide film. Furthermore, the wet cell with its thinner film is a condenser of appreciable capacitance which takes a charging current of about 0.5 ampere at 60 cycles. When the voltage reaches a certain critical value which is between 300 and 400 volts for the wet aluminum cell and between 300 and 500 for the oxide cell (or higher if the paint film is made thicker) the current is allowed to pass freely through the cells, limited only by the ohmic resistance of the cell independent of the film. Since the oxide film arrester has no dissolution of the film, as occurs in the wet aluminum cell charging is not only unnecessary, but undesirable. This extends the use of the oxide film arrester to localities where there are no attendants.

Although the wet aluminum plate becomes frosted to an appreciable thickness by the passage of current in long use, the actual thickness of the film, as represented by the critical voltage, is not changed. In the oxide film arrester, however, the film less than one 1 mil thick initially thickens up by the addition of successive spots of litharge for each successive discharge. This represents the wear on the arrester and limits its total life. Fig. 1 shows comparative volt-ampere characteristics of the oxide film arrester and the a. c. aluminum arrester. Since both of these arresters have a leakage current which wears the plates of the cells when arternating current is supplied, it is necessary, as previously stated, to place a spark gap in series with the cells. This spark gap is set at a value slightly above the normal potential of the circuit so that nothing but abnormal voltages will cause a discharge.

Mr R. S. Wright, Sudbury, Ont., writes: "I have always looked on POWER HOUSE as our own country engineer's journal, and it is up to us stationary engineers at this time to show our patriotism and support home industry."

Methods of Mounting Motors on Ceilings

By Mounting Motors Near the Ceiling or in the Roof Trusses Valuable Space is Saved and Economies Effected in Transmission Where Group Drive is Employed

By RALPH G. BRADSHAW

IT very often occurs that the most desirable location for a motor for a group drive is at or near the ceiling of the room. In such a location the motor does not occupy valuable floor space, and is immune from meddling by the unauthorized. There are two possible objections to such a location. One is that the space near the ceiling is always the hottest part of the room, which is undesirable, because a motor placed in such a location may become unduly overheated. The other objection is that unless proper provisions are made, a motor near a ceiling may be difficult to inspect and repair. The last objection can be nullified, provided proper ladders and platforms are installed, from which the inspector can work.

Where a small motor is to be placed it can be bolted, inverted, directly against the ceiling. Timbers can be secured against the ceiling, into which lag bolts, passing through the bolt holes in the motor frame, can turn. Lag bolts should, however, never be used to support a motor, hence the preferable and only dependable method of supporting a motor at or near the ceiling is to fix the supporting bolts so that they will pass entirely through the floor. The most effective way to raise an inverted motor to a position against the ceiling is to thread two lines or falls through diagonally opposite holes bored through the ceiling, as above suggested. In boring these holes care must be taken to place them so that they will exactly fit over the holes in the motor frame. The lines are passed through from the storey above to the floor of the room below. The motor to be mounted is turned upside down on the floor, and each of the two lines is threaded through a bolt hole in the motor frame corresponding in position to the hole in the ceiling above through which the line passes. Then a knot is tied in the line below the motor frame so that when the lines are pulled on the knots will sustain the weight of the motor. Then helpers on the storey above pull on the lines and draw the motor in position against the ceiling. Bolts are inserted through the remaining holes in the floor and through the motor bed plate and the nuts are set up on these bolts, holding the bed plate firmly in position. Then the lines are removed and supporting bolts are pushed through the holes in the floor from which the lines have been taken and through the motor bed plate, and their nuts turned up on them.

With larger motors it is necessary to build a shelf or platform upon which the motor may rest and upon which the inspector may stand while cleaning and adjusting the machine. Fig. 1 shows a simple motor platform that has been found very satisfactory in practice. A number of supports similar to this were used in the Omaha shops of the Union

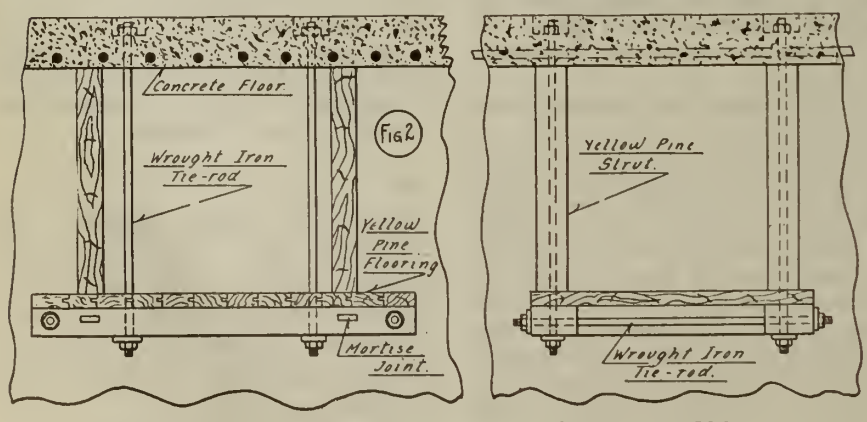

FIG. 2—MOTOR SHELF SUPPORTED FROM CONCRETE CEILING

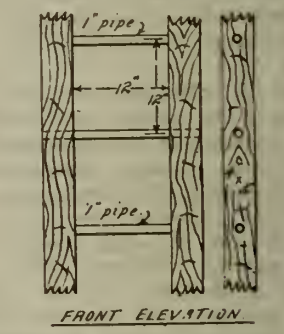

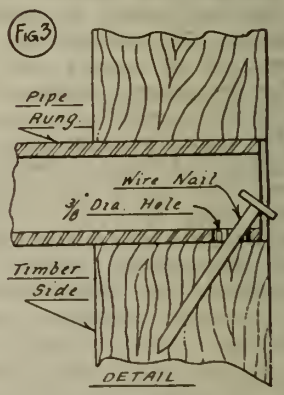

FIG. 3—CONSTRUCTION OF A LADDER WITH PIPE RUNGS

Pacific Railway. Group drive motors of outputs in the neighborhood of 20 h.p. were mounted on the platforms. It will be noted (Fig. 1) that all of the platforms were arranged along the side of the building, so that a 6x8 in. timber held to the brick wall with ⅞-in. bolts formed a support for one edge of the platform. An 8x8 in. timber formed a beam carrying the outer edge of the platform. This timber was in each case

held from the floor above by two 1¼-in. tie rods that passed vertically entirely through 8x16 floor joists. Care was taken to so locate the motor platforms that the tie rods would, in every case, pass through holes in the floor joists, because the holes in the joists in which the tie rods snugly fitted provided lateral support for the platform structure and tended to minimize vibration. A 6x8 strut was clamped in at the side of each tie rod between the platform floor and the gallery floor joists. A slot was cut in the side of each of these struts for the accommodation of the tie rod, which maintained each strut in its correct position.

A platform that has been successfully used for supporting motors to ceilings in reinforced concrete buildings is shown in Fig. 2. The tie rods pass, as they should in every case, entirely through the floor, so that they will be substantially supported from above. The timbers comprising the frame upon which the floor is laid are mortised and tenoned and are held together with iron tie rods, eliminating any possibility of the shaking asunder of the frame. Where there is a considerable side pull occasioned by a belt drive from a motor platform, it may be necessary to install braces for a platform like that shown in Fig. 2, to prevent the platform from being pulled out of its position laterally. Ordinarily, however, such braces are not necessary if the platform is well constructed and the nuts of the tie rods are set up snugly.

It is, however, essential that a good ladder, or some other means of access, be provided to every motor platform. If it is difficult for the inspector to reach the platform, the motor will probably not receive the attention that it should. A splendid form of ladder that will not wear out, and which can be readily constructed is shown in Fig. 3. The side pieces are 4x4 timbers and the rungs are 20-in. lengths of 1-in. pipe. Pipe that can not be used for any other purpose, because it is rusted, or cracked, can be utilized for rungs of a ladder of this type. The 12-in. distance between centres of rungs provides a convenient spacing, but this can be increased or decreased in accordance with the practice prevailing in the plant where the ladder is installed. The holes through the 4x4 timbers for the reception of the pipe should be so bored that the pipe will fit into them very snugly, and a nail should be driven, as shown in the detail in Fig. 3, through a hole in the end of each pipe to prevent its turning as a man mounts the ladder. The nails also keep the rungs from slipping sideways out of the timbers. The nails should always be driven in far enough so that they will not extend and cut the fingers of a man using the ladder.

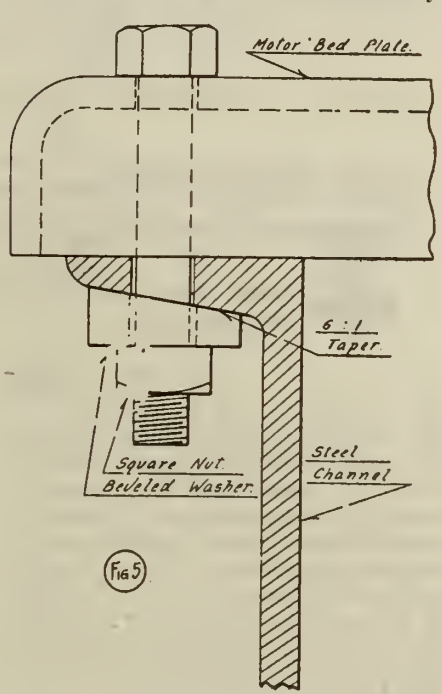

FIG. 5—DETAIL SHOWING HOW BEVELED WASHER IS USED

Ordinarily, ladders about an industrial plant are made with 2 x 4 vertical timbers, and 1 x 4 rungs and such are, of course, cheaper, in first cost at any rate, than the ladder in Fig. 3, but the rungs in wooden ladders wear out, and sometimes they break and injure a man and thereby involve a damage suit. It is for the reason that the pipe rung ladder is always safe and will practically never wear out that it is probably more economical in the long run than a wooden ladder. The pipe rungs can be cut and drilled in the pipe shop at times when the mechanics have no other work to do.
